

EMIGRATION RESTRICTIONS AND ECONOMIC DEVELOPMENT

Evidence from the Italian Mass Migration to the United States^{*}

Abstract

This article studies the impact of immigration restriction policies on technology adoption in countries sending migrants. Between 1920 and 1921, the number of Italian emigrants to the United States dropped by 85% after Congress passed the Emergency Quota Act, a severely restrictive immigration law. In a difference-in-differences setting, we exploit variation in exposure across Italian districts to this large restriction on human mobility. Using novel individual-level data on Italian emigration to the US and newly digitized historical censuses, we show that this policy substantially hampered technology adoption and capital investment. This evidence is consistent with directed technology adoption theory: an increase in the labor supply dampens the incentive for firms to adopt labor-saving technologies. To validate this mechanism, we show that more exposed districts display a sizable increase in overall population and employment in manufacturing. We provide evidence that “missing migrants,” whose migration was inhibited by the Act, drive this result.

Keywords: Age of Mass Migration, Emigration, Technology Adoption.

JEL Classification: N34, O15, O33.

^{*}This paper supersedes an earlier version circulated as “The Economic Effects of Immigration Restriction Policies: Evidence from the Italian Mass Migration to the US.” We are particularly grateful to Mara Squicciarini for her continued guidance and support. We thank Maristella Botticini, Gaia Dossi, Stefano Fiorin, Michela Giorcelli (discussant), Simon Görlach, Thomas Le Barbanchon, Nicola Limodio, Jaime Marques Pereira, Luke Milsom (discussant), Joel Mokyr, Nathan Nunn, Gianmarco Ottaviano, Sebastian Ottinger, Elena Stella, Marco Tabellini, and seminar participants at Alghero, Bari, Bocconi, CESifo, EEA/ESEM, IZA, OECD, and Warwick for insightful comments and discussions. We acknowledge financial support from Bocconi. Nicola Fontana, Marco Manacorda, Gianluca Russo, and Marco Tabellini kindly shared data with us. All errors are our own.

I Introduction

Innovation represents the most fundamental driver of productivity growth—and, hence, of long-run development—in leading-edge economies (Romer, 1990; Aghion and Howitt, 1992). In 2021, however, 88% of all patent grants originated from only six countries.¹ Most remaining nations rely heavily on technology transfer from these core countries to propel productivity growth (Griffith *et al.*, 2006). The adoption of foreign technology is, thus, a crucial determinant of long-run economic growth in developing countries, which typically operate far from the technology frontier (Suri, 2011; Bryan *et al.*, 2014).²

This paper examines how out-migration, a common defining feature of the industrialization process, influences the incentive for firms in developing countries to adopt productivity-enhancing technology, thus impacting long-term prospects of economic prosperity. More specifically, we investigate how restrictions to human mobility imposed by immigration countries impact technology adoption and investment in the emigrants’ countries of origin.³

The effects of out-migration on technology adoption are *ex-ante* ambiguous and potentially conflicting. On the one hand, emigration entails a loss of human capital—a “brain drain”—that may hamper the ability of countries to adopt new technologies (Kwok and Leland, 1982; Gibson and McKenzie, 2011). On the other, however, higher emigration rates may incentivize the adoption of labor-saving technologies by increasing the relative cost of labor (e.g., see Hicks, 1963; Habakkuk, 1962). From the perspective of directed technical adoption theory, one can interpret immigration restriction policies (IRPs) as “passive” labor market policies that increase the labor supply in targeted countries. This would, in turn, prompt the substitution of capital with more abundant—hence cheaper—labor, thus depressing investment in capital-intensive technologies. Which effect prevails is, ultimately, an empirical question.

The setting we study is the Italian mass migration, the largest episode of voluntary migration from one single country in recorded history (Choate, 2008). Between 1876 and 1925, approximately thirteen million emigrants left Italy (nearly 70% of the average Italian population in 1900); about half never returned. Italy had one of the highest emigration rates; since the 1890s, it was the leader in sheer emigration numbers (Hatton and Williamson, 1998). On average, 40% emigrants headed toward the United States, the single most common destination country and the focus of this paper. However, the Italian

¹Authors’ calculation on public data released by WIPO ([link here](#)).

²Economic historians have famously recognized that countries that industrialized relatively late, such as Germany or Italy, relied heavily on innovation produced abroad to catch up with the core industrial countries (Gerschenkron, 1962; Rosenberg, 1982). Recent literature within the tradition of endogenous growth theory embeds technology diffusion dynamics and quantifies its—substantial—contribution to productivity growth (e.g. Eaton and Kortum, 1999; Alvarez *et al.*, 2013; Buera and Oberfield, 2020; Van Patten, 2023).

³For brevity, we refer to those policies as immigration restriction policies (IRPs). Data from de Haas *et al.* (2015) suggest that IRPs have become increasingly common since the 1970s and currently account for 40% of the entire corpus of migration laws.

mass migration to the United States abruptly ended in 1921, when Congress passed the first of a series of restrictive IRPs that we refer to collectively as the “Quota Acts.” The Quota Acts defined numerical quotas on yearly arrivals from European countries, which drastically reduced the inflow of Italians in the US.⁴ Between 1920 and 1921, the inflow of Italians in the United States dropped by 85% and never recovered (see Figure 1). We exploit variation arising from this sharp and massive restriction to human mobility.

To identify the effect of this immigration restriction policy shock on economic development, we define a district-level measure of exposure to the US Quotas. A district is more exposed to the policy if a larger proportion of its emigrants had moved to the United States before 1921, conditional on the overall emigration rate. In a difference-in-differences setting, we thus compare districts with similar emigration rates and leverage variation among destination countries.⁵ Formally, our identification assumption thus requires that districts with similar emigration rates but different destinations would not have undergone different development trajectories had the Quota Acts not been enacted, *i.e.* they were on parallel trends in terms of the outcomes we consider. We provide several pieces of evidence supporting this assumption. The results are robust to instrumenting observed exposure to the US quotas with a pull shift-share instrument along the lines of Anelli *et al.* (2023).

The historical setting allows us to overcome several limitations of contemporary scenarios. First, emigration seldom flows into only a few destinations; hence, observing significant restrictive policy shifts is challenging. Second, migration dynamics are often affected by co-evolving regulations enacted by both receiving and sending countries, which were absent during the period we study (Abramitzky and Boustan, 2017). Third, it is often difficult to retrieve information on emigrants in their home country (Dustmann *et al.*, 2015).

Existing data from official statistics are not suitable for this exercise because (i) digitized US and Italian censuses and complementary historical statistics do not report the origin of Italian migrants at a granular level of spatial aggregation, and (ii) disaggregated indicators of economic performance for Italy remain scarce. We thus construct a novel dataset linking administrative records of Italian emigrants who arrived at Ellis Island between 1892 and 1930 to their district of origin, and we complement it with newly digitized detailed data from industrial and population censuses. These data allow us to document three

⁴The 1921 Emergency Quota Act restricted the annual number of immigrants admitted into the United States to no more than 3% of the number of residents from that country, as recorded in the 1910 census. The 1924 Johnson-Reed Act reduced the quota to 2% and pegged the reference date to the 1890 census. These laws explicitly targeted Southern and Eastern European countries, which until the early 1900s hardly took part in the Age of Mass Migration and whose immigrants were perceived by the public as a threat to America’s economic welfare and cultural values (Higham, 2002).

⁵This intensity-of-treatment design is closely related to the conceptual framework adopted by Abramitzky *et al.* (2023) to study the effect of the Quota Acts on the US labor market.

sets of results.

The empirical analysis proceeds in three steps. First, we establish that the Quota Acts had a tangible impact on Italian districts. Theoretically, it is possible that those who would have migrated to the United States had the policy not been enacted could move to a different country. Looking at aggregate emigration numbers (Figure 1), this seems implausible. Emigration to the United States completely dried up after 1921, but that to other countries did not. The total number of emigrants in the 1920s is roughly comparable to that in the 1880s and early 1890s before the US migration gained momentum. We formally test this “imperfect substitution” argument and find that the population in districts that were conditionally more exposed to the Quota Acts increases after 1921. The effect of the Quotas is sizable in magnitude: a 1% increase in the share of US emigrants before 1921 leads to an increase in population by more than 0.03%. This finding is consistent with previous studies documenting the spatial persistence of Italian emigration flows (Gould, 1980b; Brum, 2019; Spitzer *et al.*, 2020). More qualitative cross-country evidence confirms that emigration outflows toward countries that did not promulgate IRPs did not increase. Hence, districts supplying relatively more U.S.-bound emigrants ended up having more “missing” migrants, i.e., people who would have migrated had the Quota Acts not been enacted. This mechanism generates a spatially segmented positive labor supply shock.

Our second finding is that industrial firms in provinces more exposed to the Quota Acts substantially decreased investment in capital goods. We consistently estimate adverse effects across several measures of capital goods, ranging from firms with at least one engine to the number of installed engines and the power they generate. For instance, a 1% increase in the share of US emigrants before 1921 leads to a 0.2% decrease in the number of mechanical engines and a 0.4% decrease in the horsepower generated by installed electrical engines. All sectors within manufacturing exhibit similar decreases in capital investment. How can we reconcile the increasing population with the decreasing adoption of productivity-enhancing production technologies? We propose interpreting these findings through the lens of directed technological change theory (Acemoglu, 2002, 2007). As labor becomes a more abundant production input, firms are incentivized to forego investment in capital goods and employ more labor. In Online Appendix D, we develop a simple theoretical framework in the spirit of Zeira (1998) and San (2023) to show how employment and investment would react to a positive labor supply shock within this theoretical framework.

To test this interpretation, we study how employment across sectors reacted to the Quota Acts. First, we perform a relatively aggregate analysis of agriculture and manufacturing employment at the district level. We find that manufacturing employment increases in districts more exposed to the IRP shock. Quantitatively, a 1% increase in treatment exposure leads to an increase in manufacturing employment of more than 0.1%. We fail to detect any such effect in agriculture. Historical evidence suggests that Ital-

ian agriculture in the 1920s was organized as a heavily labor-intensive sector (Cohen and Federico, 2001). It thus seems plausible that manufacturing could be the primary beneficiary of the substantial labor supply shock. Second, we look at how different sectors within manufacturing absorbed the population increase. Analogously with the capital results, we estimate comparable increases in manufacturing employment across industries. Thus, the aggregate and sector-level employment and capital responses to the IRP shock are consistent with the predictions of the directed technical change conceptual framework.

Overall, this paper argues that immigration restriction policies should be evaluated in terms of their joint impact on the receiving and sending country. The latter, in particular, experience an increase in the labor supply, which, in turn, dampens technology adoption, thus potentially hampering long-run prospects of economic growth. Concerns about the generalizability of our findings to contemporary scenarios naturally emerge. We briefly discuss, however, that the Italian migration to the United States shares similarities with contemporary flows between developing and developed countries which, from a policy perspective, may enhance the informativeness of our findings.

Related Literature This paper is related to three streams of literature. First, we speak to the several contributions seeking to investigate the impact of emigration on sending countries, as opposed to the much more developed literature studying the economic and social effects of immigration (Clemens, 2011). Emigration has been shown to impact wages (e.g., Dustmann *et al.*, 2015), attitudes towards democracy and voting (Spilimbergo, 2009; Batista and Vicente, 2011; Ottinger and Rosenberger, 2023) and political change (Chauvet and Mercier, 2014; Kapur, 2014; Karadja and Prawitz, 2019), the diffusion of novel knowledge (Coluccia and Dossi, 2023), entrepreneurship (Anelli *et al.*, 2023), and social norms (Beine *et al.*, 2013; Bertoli and Marchetta, 2015; Tuccio and Wahba, 2018). We inform this literature by studying a different mechanism whereby emigration fosters the adoption of labor-saving technologies. We emphasize that this channel operates plausibly independently from human capital accumulation.

Second, we contribute to the literature that studies the relationship between technology adoption and the supply of production inputs. Following the seminal contributions by Hicks (1963) and Habakkuk (1962), Hornbeck and Naidu (2014), Clemens *et al.* (2018), and Hanlon (2015) all study historical settings where changes in the availability of labor and other factors of production altered the direction of innovation activity. Lewis (2011) offers similar evidence in a modern setting. Our paper is closest in spirit to Andersson *et al.* (2022), who show that labor-saving innovation emerged in response to migration-induced labor shortages in 19th-century Sweden. Similar to their paper, we emphasize the labor supply-shock mechanism. However, we focus on technology adoption and leverage exogenous variation in a DiD framework. Several studies document the importance of technology adoption as a critical driver of long-run growth, particularly in developing countries (Suri, 2011; Bryan *et al.*, 2014; Juhász *et al.*, 2020). Moreover, while Andersson *et al.* (2022) study the effect of a labor *shortage*, this paper documents how

excess labor stemming from immigration restriction policies shapes the adoption of new technologies.

Third, by its setting, this paper adds to the literature that studies technical change and diffusion of novel technologies during the Age of Mass Migration. A growing number of papers examines the short-run (Arkolakis *et al.*, 2020; Moser and San, 2020; Diodato *et al.*, 2022) as well as the long-run (Akcigit *et al.*, 2017; Burchardi *et al.*, 2020; Sequeira *et al.*, 2020) implications of immigration on US innovation. Ottinger (2020) shows that European immigration influenced US industry specialization. Moreover, we contribute to the studies that look at the Italian case. Among those, Hatton and Williamson (1998) study the aggregate determinants of Italian emigration. Spitzer *et al.* (2020) validate the Gould (1980) theory, whereby social networks exerted substantial influence on Italian emigration dynamics. Pérez (2021) compares the assimilation dynamics of Italian emigrants to the United States with those who moved to Argentina. Our contribution to this literature is twofold. Methodologically, we build the first highly comprehensive geographically disaggregated dataset of Italian emigrants during the years of the mass migration (1900–1914). We also present newly digitized district-level data from population and industrial censuses. In terms of new findings, we show that the mass migration was unlikely to have hampered the structural shift toward manufacturing. Our results suggest that the opposite impact prevailed: immigration *restriction* likely hampered economic modernization in Italy.

Outline of the paper We structure the paper as follows. Section II describes the Italian mass migration, the policies that shaped it, and the fundamental economic characteristics of early 20th-century Italy. Section III discusses our data-collection contribution and the sources. In Section IV, we detail the empirical strategy and present our three sets of results. Section V concludes.

II Historical Background

II.1 The Italian Mass Migration

The Italian mass migration (1870–1925) was the largest episode of voluntary migration in recorded history (Choate, 2008). Between 1880 and 1913, 17 million—corresponding to 65% of the Italian population in 1900—emigrated; most headed toward continental Europe and the Americas. Along with Ireland, Italy had the highest per capita emigration rate (Taylor and Williamson, 1997). Even though Bandiera *et al.* (2013) document that returns rates were equally among the highest in Europe, the Italian mass emigration has long been recognized as a focal feature of the country’s development process (Hatton and Williamson, 1998).

II.1.1 A Short History of the Italian Mass Migration

Italy was a latecomer to large-scale mass migration. Northern European countries had been experiencing substantial population outflows since the 1840s. By contrast, Italy and other Southern and Eastern European countries didn't start experiencing mass emigration until the 1880s. The country's migration patterns over 1870–1925 display substantial time variation. Until the 1880s, its emigration rate remained relatively modest, and most migrants hailed from Northern regions. Prohibitively high transportation costs and prevailing poverty in rural Southern areas largely inhibited migration from the *Mezzogiorno*. During the 1880s, Northerners chiefly moved to neighbor countries on a temporary, seasonal basis (Sori, 1979). The widespread adoption of steamships and an agrarian crisis kicked off the Southern mass emigration (Keeling, 1999). A decade later, the script had flipped: most migrants were now coming from Southern regions. Though the share of migrants from Northern regions declined as the share from Southern regions grew, emigration rates from *both areas* rose steadily from 1870 to 1913 (Hatton and Williamson, 1998). By the 1890s, Italy had become the global leader in sheer numbers of emigrants and in emigration rate, which grew from 5‰ in 1880 to a peak of 25‰ in 1913.

Italian emigration collapsed during World War 1 (WW1) but quickly regained momentum in the years immediately following the war. The epoch ended in the early 1920s when the U.S. Congress enacted restrictive immigration policies that effectively halted mass emigration to the United States. Emigration toward other transoceanic and European destinations nonetheless endured until the outbreak of WW2. In Online Appendix Table B.2, we tabulate data from official statistics on regional out-migration to the United States and other international destinations to gauge the geographical evolution of the Italian mass migration over time.

Internal migration is one last, largely overlooked component of labor mobility in Italy during the Age of Mass Migration. Current data limitations hinder a quantitative study of internal migration from 1870 to 1925. In the rest of this study, we abstract from explicitly accounting for internal migrations for three reasons (beyond data availability). First, Gallo (2012) shows that internal migrants were easily outnumbered by international migration flows, particularly during the Age of Mass Migration. We provide a quantitative assessment of this claim in Online Appendix Table B.3, which confirms that the number of international emigrants is one order of magnitude larger than internal migrants. Second, internal mobility was largely temporary and seasonal, inherently different from transoceanic migration (Gallo, 2012). Third, internal migrations reflected historically deep-rooted, persistent economic relationships between regions unlikely to influence our results on economic modernization in the 1930s.

II.1.2 Composition and Determinants of the Migratory Movements

In the 1880s, Italy was a young nation rife with regional disparities spanning cultural and economic dimensions (Smith, 1997). The resulting geographically segmented migratory patterns largely reflected this substantial heterogeneity and provided our empirical strategy's backbone. Until the early 1880s, most migrants from Northern regions moved to European countries. Most of the rest steamed across the Atlantic to Argentina and Brazil. This pattern is completely reversed for Southern migrants, whose primary destination was the United States.

To explain why destinations with low relative wage gaps, such as Argentina and Brazil, received sizeable migration inflows, Gould (1980b) hypothesizes that local emigration dynamics were driven by information diffusion. Information about emigration opportunities required time to spread across the country, and this diffusion accelerated as the volume of emigration increased. Gould (1980b) provides convincing evidence suggesting that declining regional emigration-rate inequality is consistent with this mechanism. An indirect consequence of the Gould hypothesis is that local emigration rates displayed relatively little sensitivity to economic and demographic conditions, instead featuring high persistence (Hatton and Williamson, 1998). Spitzer and Zimran (2023) further provide evidence consistent with Gould's diffusion hypothesis. They show that emigration began in a few districts in the 1870s and 1880s, then subsequently spread to nearby districts over time through immigrants' social networks. In Online Appendix A.3.3, we present some evidence that points in the same direction.

II.2 Migration Policy in Italy and the United States

An appealing feature of this context is that migratory flows from Europe to the United States remained essentially unregulated until 1921 (Abramitzky and Boustan, 2017). This section describes the key features of the historical Italian and U.S. systems of migration laws.

II.2.1 Italian Migration Policy

Newly unified Italy had virtually no emigration policy until 1873. Occasional, largely ineffective provisions were enacted between 1873 and 1887 that reflected the perceived need to deal with labor agents and recruiters, the so-called *padroni*, but did not form a corpus of migration law (Gabaccia, 2013). The first such attempt was the 1888 Crispi-De Zerbi law, which introduced and regulated the emigration contract between the migrant and the migration agency. However, the law was manifestly inadequate to deal with the waves of migration that unfolded starting in the 1890s, and it effectively failed (Foerster, 1919).

As emigration to the United States gained momentum, a new emigration law was passed in 1901 under the renewed understanding that emigration was no artificial phenomenon and could positively

affect Italy (Foerster, 1919). As such, the law sought to protect migrants from exploitation rather than restricting their movement. The law established a Commissioner-General of Emigration to oversee the protective institutions and collect data on migrants. Only companies licensed by the Commissioner-General could sell tickets, whose rates were reset every three months. Comparatively minor subsequent legislation further protected remittances (1901), strengthened the authority of the Commissioner-General (1910), and regulated citizenship (1913) (Rosoli, 1998).

II.2.2 American Migration Policy

The United States, for its part, maintained an open border between 1775 and the early 1920s, interrupted only by isolated outbreaks of anti-immigration policy interventions. During the Age of Mass Migration, some 30 million migrants entered the United States. By 1910, 22% of the labor force was foreign-born, the highest such share ever since (Abramitzky and Boustan, 2017). In 1907, the United States Congressional Joint Immigration Commission, also known as the Dillingham Commission after its chairman, was formed to study, among other things, immigrants' economic and social conditions. The Commission's 41-volume report favored "old" immigration countries such as England and Germany over "new" ones, mainly Southern and Eastern European.

When immigration ramped up again after WWI, nativist demands for restrictions surged, and the Emergency Quota Act was passed in 1921. It was modified by the 1924 Immigration Act, which further tightened immigration restrictions on second-wave countries. The 1921 Emergency Quota Act envisaged a (temporary) annual quota of 360,000 immigrants from Europe.⁶ Importantly, for our identification, entry quotas were assigned to each country as 3% of that country's nationals living in the United States in 1910, as recorded in that year's census. The 1924 Immigration Act made the quota system permanent, lowered the inflow from 3% to 2%, and shifted the census baseline year to 1890. The last provision, in particular, targets Southern and Eastern European countries that took part in the Mass Migration starting in the late 1890s, as advised by the report of the Dillingham Commission. Abramitzky *et al.* (2023) note that the 1924 Immigration Act had a highly heterogeneous impact on immigration across different sending countries. Flows from Southern and Eastern Europe were heavily curtailed because the share of foreign-born individuals from those countries who lived in the United States in 1890 was very modest. Since the 1890s, the United States had been absorbing 30% to 40% of all Italian emigration, so the Quota Acts represented a significant policy shock for Italy.

II.3 Technology Adoption and Economic Growth in Italy

Italy entered the Age of Mass Migration in the 1880s. The country was amid an agrarian crisis that followed two decades of stagnation (Toniolo, 2014). The period from 1895 to 1913 was the only time until the

⁶U.S. immigration peaked in 1907 at 1,285,349 entrants. The number of entrants during the 1910s averaged around 800,000.

1950s “economic miracle” in which Italy outperformed and narrowed the income gap with the leading industrial nations. In the 1920s and 1930s, during the Fascist period, Italy was still a mainly agricultural country, featuring low income per capita and stagnating productivity (Cohen and Federico, 2001). During the first half of the Fascist *Ventennio*, economic policy was aimed primarily at fiscal and monetary consolidation. Agricultural policy—which formed an integral part of the Fascist propaganda—centered on boosting agricultural productivity, which had been stagnating since WW1, and draining marshlands. However, sheer numbers attest that agrarian policies resulted in neither substantial intervention nor sizeable progress (Zamagni, 1993). Growth slowed after 1925, and regional disparities widened (Cohen and Federico, 2001). Historical evidence is thus consistent with our finding that following the 1921–1924 U.S. emigration restrictions, Italy underwent a period of economic distress and rising regional inequality.

We relate the migration shock to diminished investment in capital goods, especially technologically advanced ones, and a shift to labor-intensive production routines. Italy operated far from the technological frontier throughout the period, and skill premia actually *declined* from the 1890s onward (Vasta, 1999). Similarly to contemporary developing countries, Italy lagged behind large industrial nations in research-and-development expenditures, and it imported substantial amounts of foreign technology, both patents and machinery. Italian firms bundled different vintages of capital whenever possible, adding new machines to existing ones instead of renovating the whole stock (Cohen and Federico, 2001). The large pool of unskilled workers made it more profitable for Italian entrepreneurs to adopt labor-intensive technologies relative to the highly capital-intensive German and British ones. Consistent with this narrative, we find that the migration policy shock increased the stock of unskilled workers in regions with high emigration. There, firms opted out of investment in capital goods and became more labor-intensive, thus hampering the modernization process they had been undergoing before the Quota Acts.

III Data

Our analysis spans the years 1881 to 1936. We collect data from a number of sources; data are organized by census years and analyzed at the *circondario* (henceforth, “district”) level if available. Otherwise, the units of observation are provinces.⁷ In 1921, there were 216 districts and 69 provinces, each consisting of a variable number of municipalities (see Online Appendix section A.1 for a complete description of

⁷Population censuses were taken in 1881, 1901, 1911, 1921, 1931, and 1936. Manufacturing censuses were taken in 1911, 1927, and 1936. Districts were instituted in 1859 as the middle administrative unit between municipalities and provinces. They had mainly statistical and judiciary purposes and were granted little administrative autonomy. Districts were organized in provinces, which encompassed between one and five districts. In the Online Appendix section A.1, we discuss in more detail the sources that we digitized and present a visual summary of all the variables we analyze. In Online Appendix A.2, we describe how the final estimation samples are constructed.

the data). Because districts were abolished in 1927, all subsequent district-level data are collected at the municipality level and aggregated at the 1921-district boundaries. We adopt the geographical cross-walk procedure described by Eckert *et al.* (2020) to ensure that we work with consistent 1921-border district and province geographies. Table 1 reports summary statistics for the variables in our final dataset. Online Appendix Table A.1 lists the source and coverage of each variable in the final dataset.

III.1 Emigration Data

Italian official emigration statistics provide insufficient information because out-migration flows were recorded at the province level (Hatton and Williamson, 1998). This poses two challenges. First, we would rather work with more granular geographical units than provinces whenever possible. Second, and more crucially, we need emigration data broken down by emigration country. These limitations naturally preclude the use of official statistics for an econometric exercise. We nonetheless digitize province-level emigration outflows and use them to construct overall emigration rates and validate the series we derive from the dataset that we assemble.⁸

To overcome these issues, we collect administrative records of Italians who entered the country between 1892 and 1930 through the Ellis Island immigration station.⁹ This was by far the largest, though not the only, immigration gateway during this period.¹⁰ Administrative records report, for most migrants, name and surname, year of arrival, age, municipality of origin, and sailing ship. This study concentrates on the migration year and the municipality of origin. Ultimately, we collected approximately 2.7 million individual observations from 1890 to 1930.

Because U.S. officials recorded the data, the municipality variable displays frequent coding errors. We perform manual and automated trimming of the raw data and geo-code each municipality to precise geographical coordinates. We can match 1.6 million migrants to their municipality of origin. Among those, 800,000 municipalities are coded with no error. We then map each municipality to the district it belonged to in 1921 through historical GIS boundary files and compute the resulting aggregate U.S. emigration.¹¹ To the best of our knowledge, this is the most comprehensive data spanning the whole

⁸We construct district-level emigration rates from official statistics assuming that emigration rates were constant within each province and assigning emigrants in proportion to district population.

⁹These records are freely available at heritage.statueofliberty.org. We run queries over a comprehensive pool of 20,000 Italian surnames over the 1890–1930 period. In Online Appendix section A.3.2, we document that our newly constructed series correlates well with existing—albeit less granular—emigration data from official statistics.

¹⁰According to official U.S. statistics, between 1892 and 1924, a total of 14,277,144 migrants entered the country through Ellis Island, out of a total immigration inflow of 20,003,041 (Unrau, 1984, p. 185). Thus, Ellis Island alone accounted for 71.4% of the total immigrant inflow. Some 95% of all Italian immigrants passed through Ellis Island.

¹¹Online Appendix A.3.1 discusses the methodological details, including the frequency of missing data on immigrants' municipality of origin.

Age of Mass Migration for Italy, at this level of aggregation.¹² We validate this dataset with coarser data available from official statistics as detailed in Online Appendix A.3.2. There is a positive, statistically significant, and large correlation between the Ellis Island data and official statistics, which remains stable throughout the estimation period.

Figure 1 plots the overall country-level yearly inflow of immigrants who landed in Ellis Island from 1892 to 1930. Emigration took off in the mid-1890s and peaked between 1905 and 1913. It collapsed during World War 1 (WW1), quickly regained momentum in 1920, then was definitively shut down by the Quota Acts in 1921 and 1924. Our data are consistent with comprehensive U.S. immigration data and overall Italian migration patterns (Brum, 2019; Sequeira *et al.*, 2020). In Figure 2, we plot the geographical distribution of migrants across districts. Panel 2a displays the variation in the emigrants-to-population ratio, i.e., the emigration rate. Panel 2b reports the unconditional variation in the U.S. emigrants-to-overall emigrants ratio, which is the baseline measure for treatment exposure. Online Appendix A.3.3 presents some further stylized facts that the data allow documenting.

III.2 Population and Manufacture Censuses

The population of each municipality was compiled by the Italian Statistical Office (ISTAT). We aggregate it by district and province for each census between 1881 and 1936.¹³ We compute the k -urbanization rates as (i) the share of the population residing in cities with at least k -thousand inhabitants and (ii) the share of cities with at least k -thousand inhabitants. These tables also contain the altitude and area of each municipality and an indicator variable returning value one for towns near the sea. We collapse the first two at the district and province level, weighting by municipality population and tag districts and provinces with access to the sea.

We construct manufacturing and agriculture employment series from disaggregated data listed in census records. These are available at the district level before 1921 and the municipality level afterward. For consistency, we recast them at the district level throughout the sample period. Agriculture employment is not reported in the 1931 population census. Until 1921, population censuses contain sector-level employment data for manufacturing firms at the district level. After that, the same variables are reported in the manufacturing census at the province level. Thus, we can observe sector-level manufacturing employment at the province level throughout the sample period.

Manufacturing censuses contain detailed information on the quantity and quality of capital em-

¹²The only other geographically disaggregated data available to date for this period are those collected by Brum (2019) who, however, focuses on the pre-1900 period. Our dataset is thus the only one covering the years when the bulk of the mass migration occurred (1900–1914).

¹³Population censuses were taken in 1881, 1901, 1911, 1921, 1927, and 1936. Manufacture censuses were taken in 1911, 1927, and 1936. Data in manufacturing censuses are only available at the province level.

ployed in each province by manufacturing firms in 1911, 1927, and 1937. We collect within-manufacturing sector-level data on (i) the number of operating firms, (ii) the number of operating firms employing inanimate horsepower, (iii) the number of mechanical engines, (iv) the number of electrical engines, (v) the amount of horsepower generated by mechanical engines, and (vi) the amount of horsepower generated by electrical engines. We distinguish between electrical and mechanical engines because the former were at the forefront of technological progress (David, 1990). This allows us to disentangle the possibly differential impact of the labor supply shock induced by the migration shock on different technology vintages.

III.3 Other Data

Italy participated in WWI between 1915 and 1918. Because the war took place between two census years and ended just three years before the Emergency Quota Act, it can potentially confound our estimates. We, therefore, collect WW1 death records to measure the geographical variation in the cost imposed by the war across districts.¹⁴ The dataset provides rich information on Italian military personnel who died during WWI. Importantly for our analysis, it includes the municipality of origin of each soldier. Because we conduct the analysis at the district level, we collapse the dataset from municipalities to 1921 districts, and we measure the war's severity in a given district as the ratio between deaths and population in 1910.

To construct the instrumental variable, we use aggregate information on US GDP and industrial production. These are constructed by Maddison (2007) and Davis (2004), respectively.

To account for changes in market access, we digitize the entire Italian railway network over the 1839–1926 period.¹⁵ We know all the stations it is connected to for each railway section. Stations are generally labeled in terms of the municipality they were located in. Further details are included for stations located in municipalities with more than one station. We also know the exact date when each trunk was built and opened to public use, the distance it covered, and the traction system the trains employed. We use these data to construct the Italian railway network. To capture its evolution over time, we take snapshots of the network at decade frequency.

IV Empirical Strategy and Results

This section presents the empirical strategy that we adopt to identify the effects of the Quota Acts and provides evidence that supports the validity of the research design. Then, we present and discuss the

¹⁴Death records were compiled by the Fascist regime for propaganda purposes. They are available at cadutigrandeguerra.it. This dataset is maintained by the *Istituto per la storia della Resistenza e della società contemporanea*. Acemoglu *et al.* (2022) were among the first to use it in the economics literature.

¹⁵The data come from the volume *Sviluppo delle ferrovie italiane dal 1839 al 31 dicembre 1926*, edited by the Italian Statistical Office (*Ufficio Centrale di Statistica*) in 1927. To our knowledge, this is the first paper to use these data.

key findings of the paper and the possible limitations of the analysis.

IV.1 Empirical Approach

The empirical analysis hinges on the observation that areas whose emigrants were more likely to settle in the United States before 1921 would be more exposed to the Quota Acts. This implicitly assumes that emigrants do not perfectly substitute the United States with other—internal or international—destinations. The first step of the analysis validates this assumption. This section, however, takes it as valid and explains how to leverage it to causally estimate the labor market effects of immigration restriction policies.

IV.1.1 Measuring Exposure to the Quota Acts

In principle, districts with a larger share of emigrants headed toward the United States before 1921 would be relatively more exposed to the Quota Acts shock. Formally, let d and t denote a district and a year. Exposure to the Quota Acts would read out as follows:

$$\text{Gross Quota Exposure}_i \equiv \sum_{t=1900}^{1914} \frac{\text{US Emigrants}_{it}}{\text{Population}_{i,1880}} \quad (1)$$

where US Emigrants_{it} and $\text{Population}_{i,1880}$ denote, respectively, the number of emigrants who settled in the US and who originated in district i in year t , and population before the mass migration begun (in 1880). The baseline definition (1) includes the years 1900-1914 because municipality data before 1900 and after 1921 are less comprehensive (see Appendix A). We also exclude the years of WW1 because the large drop in emigration rates during the war years could be correlated with district characteristics, such as distance from emigration ports. In some robustness checks, we enlarge the period used to construct the treatment.

However, if we were to leverage variation in (1), we would be comparing districts with very different emigration rates. If the decision to emigrate were correlated with other—possibly unobserved—characteristics, then the resulting estimates would conflate this underlying spurious association. We thus decompose (1) in two margins as follows:

$$\text{Gross Quota Exposure}_i = \sum_{t=1900}^{1914} \underbrace{\frac{\text{US Emigrants}_{it}}{\text{Emigrants}_{it}}}_{\text{Quota Exposure}_{it}} \times \underbrace{\frac{\text{Emigrants}_{it}}{\text{Population}_{i,1880}}}_{\text{Extensive Margin}_{it}} \quad (2)$$

The first term in the summation denotes US emigrants as a share of the total number of emigrants; the second term, in turn, expresses the overall number of emigrants as a share of the pre-mass migration population.

Evidently, (1) and (2) are entirely analogous. However, recasting the definition of Quota exposure in (2) is useful for illustrating the empirical strategy. Our key idea is to exploit variation in the intensive

margin of US emigration holding fixed the extensive margin. In other words, the identifying variation we exploit arises by comparing districts with similar emigration rates, whose emigrants settle in different destination countries.

IV.1.2 Baseline Difference-in-Differences Model

Throughout the paper, we estimate variations of the following double-difference (DiD) Poisson regression:

$$\mathbb{E}(y_{it}|\mathbf{X}_{it}) = \exp \left[\alpha_i + \beta_t + \gamma \times \text{EM}_i \times I(t \geq 1921) + \sum_{\tau \neq -1} \delta_\tau \times I(t = 1921 - \tau) \times \text{QE}_i \right] \quad (3)$$

where $\mathbb{E}(\cdot)$ denotes the expected value of a generic outcome y conditional on a set of baseline controls \mathbf{X} ; terms α_i and β_t capture, respectively, unit and time fixed effects, and $I(\cdot)$ are indicators for each period since the Quota shock. The term (QE) is the logarithm of the net Quota Exposure metric defined in (2). We estimate (3) as a Poisson regression to account for the non-normality of the outcome and the presence of zeros, particularly when looking at capital investment outcomes. Importantly, equation (3) controls for an interaction term between the log-cumulative emigration rate (EM) and a post-Quota indicator variable. This ensures that the DiD estimators $\{\delta_\tau\}$ compare districts with similar emigration rates. In the baseline analysis, \mathbf{X} contains an indicator variable for southern regions interacted with a post-Quota indicator to account for potential heterogeneity within the South. In several robustness, however, we enrich the set of included controls.

The identification assumption that model (3) requires can be stated in terms of conventional parallel trends. Absent the Quotas, units with conditionally more US emigrants would not have displayed different patterns in y compared with districts with fewer US emigrants. While this assumption is not testable, throughout the paper, we estimate pre-treatment coefficients that are never statistically different from zero throughout the paper. This supports the parallel trends assumption.

In Table 2, however, we provide one additional exercise to gauge the validity of the research design. In each line, we report the average value of a given variable for districts (Panel A) and provinces (Panels B and C) above and below the median in 1901 and in 1911 (respectively, columns 1 and 5 and 2 and 6). In columns (3) and (7), we compute these simple means, controlling for the emigration rate. We find that observation units are comparable along almost all variables in both years. Treated districts are smaller in terms of population, and manufacturing firms there employ fewer mechanical engines. Even though districts appear to be comparable in both pre-treatment periods, it should be noted that the plausibility of the identification assumption behind model (3) only requires that treated and non-treated districts were on the same trend before the Quota shocks.

To avoid the pitfalls of the DiD estimator with continuous treatments reported by Callaway *et al.* (2021), we always report estimates of model (3) where the intensive margin is coded as a binary variable

returning value one for districts above the median value, and zero for districts below the median.

IV.1.3 Instrumental Variable for Quota Exposure

To provide more solid evidence in favor of a causal interpretation of our estimates, we construct a simple shift-share instrument to predict actual US emigration. It exploits pull variation arising from the state of business cycles in the US, as is common in the literature (among others, see Anelli *et al.*, 2023). Formally, it is

$$\text{Predicted Quota Exposure}_i \equiv \sum_{t=1900}^{1914} \sum_{\tau=1892}^{1899} \text{US Emigrants}_{i,\tau} \times \text{US GDP Growth Rate}_t \quad (4)$$

where the exposure term denotes the number of US emigrants before the estimation sample and the term US GDP Growth Rate_{*t*} is the growth rate of US GDP between years *t* and *t* − 1.

The validity of the shift-share design hinges on the exogeneity of the business cycle fluctuations (Borusyak *et al.*, 2022). Because this is a setting with a single series of shocks, the instrument features “incomplete shares” because the district-level exposure shares do not sum up to one. By including unit fixed effects in (3), we control for time-invariant unobserved heterogeneity at the district level, which may correlate with exposure to the state of the US business cycle. By contrast, the endogeneity of the first term in the summation (4) does not preclude the instrument’s validity.

The assumption of shock exogeneity requires that changes in US GDP only affected districts or provinces through their impact on migration flows. While this assumption cannot be tested, we show that there is no pre-Quota statistically significant correlation between the instrumented intensive migration margin and the outcome variables. These imperfect tests support the validity of the parallel trends assumption in the instrumented difference-in-differences framework.

In Figure 3, we check that actual and predicted US emigration rates are positively correlated. From (4), we construct a yearly district-level series of the predicted US emigration rate. In the baseline regression (3), however, we exploit cross-sectional variation arising from the overall US emigration rate over time. We thus check the instrument’s relevance in a panel setting, where each district is observed yearly, and in the cross-section, where each district is observed once. In Panel (3a), we report the first exercise: red dots only include the baseline controls included in (3), whereas the blue dots include district fixed effects. Instead, panel (3b) refers to the second exercise. Here, we cannot include district-level fixed effects because the underlying variation is cross-sectional. Hence, the blue dots include region-fixed effects. Both exercises reveal a strong, positive, and significant correlation between the instrument and observed US emigration rates. We tabulate this exercise and additional checks in Online Appendix Table B.1.

IV.2 Population Increases in Districts More Exposed to the Quota Acts

The first step of our argument maintains that areas more exposed to the US Quota Acts experienced an unexpected population increase. Implicitly, this requires that not all those who would have migrated to the United States had the Quotas not been promulgated would settle in a different country. This “imperfect substitution” argument can be tested and quantified empirically. If the US and other countries were perfectly substitutable, we would expect to find no effect of exposure to the Quotas on population.

To assess the validity of the imperfect substitution hypothesis, we estimate model (3) using population as the outcome variable. Table 3 reports the results. We find that districts more exposed to the IRP shock display a larger population after 1921. The effect remains quantitatively unchanged if we focus on the sub-sample of Southern districts, where exposure to the Quotas was generally higher (column 2).¹⁶ Importantly, in columns (3–4), we repeat the estimation using a binary treatment for districts below and above the median US emigration rate to avoid issues related to continuous treatment DiD designs. Finally, in columns (5) and (6), we include region-by-decade and province-by-decade fixed effects to account for time-varying unobserved heterogeneity non-parametrically. All these specifications yield quantitatively consistent results. A 1% increase in exposure to the Quota Acts delivers a 0.03% increase in population. To put it differently, we estimate that 80% of foregone migrants remained in more severely affected areas.

The validity of the DiD design hinges on a standard parallel trends assumption. This requires that if the US had not promulgated the Quota Acts, the population would have evolved similarly in districts with relatively higher or lower US emigration rates. To gauge the sensibility of this assumption, we estimate model (3) as a generalized DiD using the binary treatment interacted with time dummies. Figure 4 reports the estimated dynamic treatment effects. We find that districts with above- and below-median exposure to the Quotas did not statistically differ before 1921. This supports the parallel trends assumption. We estimate a positive effect of the Quotas already in 1921, which persists for at least 15 years. The immediacy of the impact of the Quotas is not surprising. As highlighted in Figure 1, US emigration collapsed following WW1. Moreover, the provisions of the Act became strictly and immediately enforced (Abramitzky and Boustan, 2017).

We repeat the exercise using the predicted US emigration rates from (4) to reduce further concerns about treatment non-excludability. Columns (7–8) report the estimated treatment effects, which confirm the baseline results.

¹⁶By “Southern” districts, we mean areas in the NUTS-2 ITF and ITG regions, which correspond to the former Kingdom of the Two Sicilies.

IV.3 Capital Investments Decrease in Districts More Exposed to the Quota Acts

How did the increased population interact with technology adoption and investment? In this section, we show that investment in labor-saving, possibly productivity-enhancing technologies decreased in areas more exposed to the shock. To do so, we estimate model (3) using several proxies of capital investment as outcome variables. We distinguish between firms, firms with at least one installed engine, mechanical and electrical engines, and mechanical and electrical horsepower generated by the respectively installed engines. The data cover manufacturing firms only.

Table 4 reports the estimated effect of exposure to the Quotas on capital investment. Panel A refers to the observed US emigration rate, whereas in Panel B, the treatment is the predicted values from (4). We find that investment in physical capital decreased in areas more exposed to the Quotas. This finding is confirmed across all the imperfect proxies available. In particular, we estimate larger treatment effects for electrical engines and horsepower. This is particularly striking, as David (1990) and Mokyr (1998) note that electrical engines stood as a major defining technology of the Second Industrial Revolution, which could yield sizable productivity advantages. Gaggl *et al.* (2021), moreover, show that electrification in the US was a catalyst for urbanization and structural transformation. In terms of magnitude, we estimate that a 1% increase in exposure to the Quota Acts, for instance, leads to a 0.2% decrease in mechanical engines and a 1% drop in electrical ones.

Figure 5 displays the associated dynamic DiD coefficients. Unfortunately, the data are available for three points in time only. Of these, 1911 is the only pre-treatment observation. We thus cannot estimate pre-treatment coefficients. Instead, in Table 2, we show that treated and control provinces were similar along all outcome variables except mechanical engines in 1911. All variables decreased in 1927: the effect remains persistent for electrical engines, while it appears to be shorter-lived for mechanical ones.

Thus far, we grouped all manufacturing sectors. The data, nonetheless, allow us to undertake a more disaggregated analysis. We report the results in Figure 7. Each “Capital” panel reports the estimated effect of the Quotas on each capital indicator for a given manufacturing sector. For readability, the coefficients are all standardized. The reaction to the population shock does not exhibit sizable heterogeneity across industries. Capital investment decreases in all sectors except for chemical manufacturing.

IV.4 The Quota Acts as Passive Labor Market Policies

Why did investments in capital and technology decrease in areas more exposed to the Quota Acts? We advance and validate the hypothesis that the immigration restriction shock triggered directed technical adoption mechanics *à la* Zeira (1998) and Acemoglu (2002). Under the imperfect substitution hypothesis, which we validated in section IV.2, areas that had been sending relatively more migrants to the United States are, in fact, subject to a larger labor supply shock because a relatively larger fraction of people

who would have emigrated are prevented from doing so. This positive labor supply shock decreases wages, which triggers firms' incentive to substitute capital with labor. We formalize this argument in Online Appendix section D.

To test this mechanism more formally, we study how manufacturing and agriculture employment reacted to the shock. We look at manufacturing and agriculture because, together, they account for more than 80% of overall employment. In section II, we noted that Italian agriculture in this period was labor-intensive and not mechanized (Cohen and Federico, 2001). The directed technical adoption narrative would thus predict that the labor supply shock generated by the Quota Acts would primarily flow into increased manufacturing employment.

We test these hypotheses in Table 5, which reports the results of the baseline DiD regression using employment in manufacture (Panel A) and agriculture (Panel B) as the dependent variables. Manufacturing employment increases in areas more exposed to the immigration restrictions shock. Quantitatively, a 1% increase in the share of US emigrants leads to a more than 0.1% increase in the number of individuals employed as manufacturing workers. This result holds within the sub-sample of Southern districts (column 2), re-coding the treatment as a binary indicator (columns 3–4) and including region-by-decade and province-by-decade fixed effects. Importantly, these hold when using the predicted exposure to the Quota Acts instead of the measured treatment. By contrast, we fail to obtain a stable estimate for the treatment effect of the Quotas on agriculture employment. We find suggestive evidence indicating a potentially negative effect, but this does not appear to be robust throughout the specifications nor when using the instrument. Overall, Table 5 provides solid evidence that manufacturing employment increased in areas more exposed to the Quotas.

As usual, we report the flexible difference-in-differences estimates in Figure 6. We confirm that treated and control districts were not statistically different before 1921 in terms of either manufacturing or agriculture employment. Manufacturing employment increased after the Quotas. The effect is persistent as it lasts at least until 1936. In this specification, agriculture employment decreases in districts more exposed to the treatment. Because manufacturing employment increases proportionally more than population, our estimates may indicate some reallocation of the workforce out of the agriculture sector into manufacturing.

We can break up manufacturing employment by sector, although at the province aggregation level. As in section IV.3, we do not uncover substantial heterogeneity across sectors. Employment increases in all industries, although marginally less so in textiles. Overall, this confirms that a positive labor supply shock is associated with a decrease in capital investment in all manufacturing sectors.

IV.5 Robustness Checks

This section summarizes the robustness checks, which we presented in Appendix C. We provide evidence that the baseline estimates are robust to alternative definitions of quota exposure, to the inclusion of several covariates controlling for both push and pull factors, to the exclusion of specific parts of the sample, and to the use of different methods to estimate the standard error.

Since measured quota exposure may be subject to mismeasurement, in Tables C.1, C.2, C.3, and C.4 we show that the results are robust to alternative definitions. The first concern is that our results might be driven either by remote migration patterns or by more recent migration closer to the introduction of the quotas. We address these concerns by constructing two measures of quota exposure which assign increasing or decreasing weights on more recent out-migration flows. In addition, we also exclude all migrants that left before 1900. As a further test, we construct our measured quota exposures using migration to the US that happened before the first Quota Act in 1921. Last, as discussed in Section III, though emigration collapsed during WW1, it did not completely dry out. During the war, districts closer to emigration ports are, in fact, disproportionately represented relative to previous shares, possibly because of their geographic position. To control for this, we restrict the sample of US emigration to the years before the outbreak of WWI. In all cases, we find that all our baseline results hold.

In Tables C.5, C.6, C.8, and C.9 we show that our baseline results are robust to the inclusion of a large set of covariates measured before the Acts, interacted with a post-Quota indicator variable, as further controls. These unit-specific control variables are the literacy rate in 1901, measured as the share of people who could read relative to the district's overall population; the urbanization rate in 1901, measured as the share of people living in towns with more than 10,000 inhabitants in the district; the altitude at which the district is located; an indicator variable that returns a value of one if the district has access to the railway network before 1901;¹⁷ the number of deaths due to World War One relative to population in 1901.¹⁸ In order to control for pull factors, in some specifications, we explicitly control for an interaction between US GDP, which serves as an indicator of the business cycle, and quota exposure. All results remain quantitatively unchanged.

In the above-mentioned Tables and in Table C.7, we also show the robustness of our results to these specifications when using the shift-share instrument as treatment.

In addition, we test that our results are robust to the exclusion of specific parts of the sample. In Figures C.2 and C.4, we show that the baseline estimates are not driven by any specific region, as regression

¹⁷For province-level analyses, we use the share of municipalities in the province that had access to the railway network before 1901

¹⁸Shares are expressed relative to the population in 1911 for province-level regression, as 1911 is the first decade of observation for analyses at that level.

coefficients remain stable irrespective of the region that we exclude from the estimation sample.

In Figures C.1a, C.1b, and C.1c, we compare the baseline estimated standard errors with a battery of alternative estimators. Among others, we employ the correction suggested by Conley (1999) to allow for time and spatial autocorrelation. The significance of the baseline results remains largely unaltered.

IV.6 Discussion and Limitations of the Analysis

In this section, we discuss some alternative mechanisms that could be compatible with our findings, and we touch on how data limitations might preclude some additional and potentially relevant analysis. We then briefly elaborate on the external validity of our results.

Human capital spillovers ignited by out-migration have traditionally received sizable attention in the literature. Evidence by Spitzer and Zimran (2018) suggests that Italian emigrants to the United States were positively selected within Southern regions, implying that emigration was exerting a “brain drain” effect on Southern Italy. Under this interpretation, our estimated effects of the Quota Acts would be partially confounded by human-capital dynamics triggered by the IRP shock. More specifically, the drop in capital investment and technology adoption might be driven by substitutability between capital goods and the upper tail of the skill distribution of workers rather than by directed technical adoption. Even though this mechanism does not necessarily conflict with the one we propose, we view this as second-order in our setting for two reasons. First, we estimate employment gains and capital investment losses in First Industrial Revolution, traditionally low-skilled and labor-intensive sectors. Hence it is unlikely that high-skilled workers would be comparatively more productive there. Second, we run a battery of robustness checks—see Online Appendix Tables C.5, C.6, C.8 and C.9. When we include the literacy rate as a proxy for average human capital in our regressions, results hold.

Along with the brain-drain effect, remittances are a traditionally major research topic within the emigration literature. Despite sizable global flows, Clemens (2011) argues that remittances can have, at best, a second or third-order effect on economic growth in sending countries when compared to the welfare effects of immigration restriction barriers. Building on this insight and given data limitations, we abstracted from including remittances in our analysis. Remittances nonetheless represent a competing mechanism. More exposed districts were receiving more remittances before the Quota Acts. Hence they suffered the most from the border closure. Inasmuch as within-household cash transfers result in aggregate savings, remittances may accrue to overall investment dynamics (Rapoport and Docquier, 2006). A large literature has nonetheless documented that remittances are largely spent on consumption and invested in human—rather than physical—capital (for a review, see Yang, 2011). A more sensible interpretation could be that remittances fostered literacy (e.g., Fernández Sánchez, 2022). Exposed districts would have thus suffered from a relative drop in skilled workers following the Acts, and the labor force

would have reshuffled toward unskilled sectors. This pattern would thus move in the opposite direction of the reverse-brain-drain effect. Under this interpretation, this channel does not conflict with the one we propose. If anything, it augments the relevance of exposure to the Quota Acts in generating an excess supply of workers, which triggered the directed technical incentive to abandon investment in physical capital.

One reason precluding a causal interpretation of our estimates would be that—even when conditioning on the decision to emigrate—the choice of *where* to emigrate was systematically correlated with factors inducing an underlying correlation with local economic development. We provide and discuss evidence throughout this paper against this interpretation. Historical scholarship, however, notes that assimilation patterns of Italian immigrants in the United States and Argentina during this period substantially differed (Klein, 1983).¹⁹ If this was caused by pre-migration differences in characteristics, then our identification scheme may fail. Using detailed data from censuses and passenger lists, Pérez (2021) nonetheless documents that the “success” of Italians in Argentina compared to Italians in the United States was unlikely to be caused by pre-migration differences in observable characteristics between the two groups. Emigrants to Argentina and the United States were essentially indistinguishable in terms of occupation and literacy rate, the only difference being that the former chiefly originated from Northern regions, whereas the latter mostly came from Southern areas. Selection patterns across the two groups do not display sizable differences, providing solid evidence in favor of our identification assumption.

Data limitations prevent us from studying two additional, potentially interesting variables, namely wages and output (productivity). Studying wages would be informative because directed technical adoption hinges on the relatively more abundant labor becoming relatively cheaper. An analysis of wages could reveal this pattern, which we currently implicitly assume. Geographically disaggregated data on wages, unfortunately, do not exist. Productivity would, in turn, be key to investigating the welfare effects of the Quota Acts. However, disaggregated data on output were not recorded until 1936; hence, we lack a time series covering the period we study.

It is not obvious that our results lend themselves to further generalization. Some similarities with contemporary settings nonetheless emerge. In terms of emigrant selection, the average Italian emigrant to the United States was slightly positively selected, left a rural area, and took on unskilled industrial jobs once in the United States (Sequeira *et al.*, 2020). This description is remarkably similar to contemporary emigration from poor countries, whereas it is starkly different from emigration from rich countries (e.g., Gibson *et al.*, 2011). While we do not claim that all our findings generalize to contemporary migration relationships, the evidence presented in this paper indicates that IRPs should be evaluated in terms of their

¹⁹Argentina and the United States were the two leading destinations for Italian emigrants in this period. Klein (1983), among others, noted that Italian immigrants in Argentina had higher home-ownership rates and were more likely to be employed in skilled occupations compared to Italians in the United States.

joint effects on sending and receiving countries beyond remittances and human-capital deprivation, as is standard in the existing literature.

V Conclusions

The adoption of foreign technology is a crucial driver of economic growth for developing countries, which typically operate far from the technology frontier (Eaton and Kortum, 1999; Suri, 2011). This paper explores the relationship between technology adoption and out-migration, a common feature of the development process.

We study the Italian mass migration to the United States between 1892 and 1936 using novel individual-level data on Italian immigrants and newly digitized census data. Between 1921 and 1924, the U.S. promulgated two immigration restriction policies—the “Quota Acts”—which completely halted the inflow of Italian immigrants. Comparing districts with similar emigration rates but different destinations, we leverage identifying variation in exposure to the Quota Acts to estimate the impact of immigration restriction laws in a difference-in-differences framework.

We document three facts. First, we find that the population increased in areas that were comparatively more exposed to the Quota Acts. This finding supports an “imperfect substitution” narrative whereby immigration restriction policies generate foregone emigration because those who would have migrated do not—or cannot—substitute the restricted location with alternative destination countries. We thus interpret immigration restriction policies as “passive” labor market policies that increase the supply of labor in the countries they target. Second, we show that firms in treated locations decreased capital investment and technology adoption, particularly in relatively more advanced technology vintages. How can we reconcile a positive labor supply shock with depressed investment in productivity-enhancing capital? We argue that the immigration restriction policy triggered directed technical change incentives (Zeira, 1998; Acemoglu, 2002). Firms face an incentive to substitute capital with more abundant, hence cheaper labor. To validate this hypothesis, we show that manufacturing employment increased in the districts more exposed to the Quotas. These dynamics operated in each manufacturing sector. We find no such effect on agriculture, which was already heavily labor-intensive before 1921.

This paper presents novel evidence that out-migration can act as a driver of technology adoption, thus potentially empowering long-run economic growth. We emphasize that this channel operates plausibly independently on “brain drain” effects. It also suggests that immigration restriction policies enacted by immigration—typically developed—countries may threaten and hamper the modernization of emigration—typically developing—ones. Our findings thus inform policymakers about the potential long-term consequences of seemingly domestic policies.

TABLE 1. DESCRIPTIVE STATISTICS

Notes. This Table reports summary statistics for the main variables used in the paper. Data in Panel A are tabulated from population censuses; data in Panel B and C are digitized from manufacturing censuses. Variables in Panels A and B are reported in 10,000 units unless otherwise specified; variables in Panel C are reported in 1,000 units. All variables are cross-walked to consistent 1921 district (Panel A) and province (Panels B and C) borders.

TABLE 2. COMPARISON OF TREATED AND CONTROL DISTRICTS

Notes. This Table compares the main variables in treated and non-treated units in 1901 (columns 1–4) and 1911 (columns 5–8). In Panel A, the units of observation are districts; in Panel B and C, the units of observation are provinces. Columns (1) and (5) report the mean value of each variable for units with below-median exposure to the Quota Acts; columns (2) and (6) report the same statistic for the group above median exposure. Columns (3) and (7) report the difference between the two groups controlling for the emigration rate and an indicator variable for Southern regions. Columns (4) and (8) report the associated robust standard errors.

***: $p < 0.01$, **: $p < 0.05$, *: $p < 0.10$

TABLE 3. EXPOSURE TO THE US QUOTA ACTS AND POPULATION

Notes. This Table reports the estimated effect of district-level exposure to the US Quota Acts on population. The unit of observation is a district observed at a census-decade frequency between 1881 and 1936. In columns (1–2) and (5–6), the treatment is an interaction between a post-Quota (1921) indicator variable the Quota Exposure metric. In columns (3–4), we interact the post-Quota indicator with a dummy returning value one if district-level exposure to the Quota Acts (measured as the ratio between US and overall emigrants) is above the median, and zero otherwise. Columns (7–8) substitute measured Quota exposure with the shift-share instrument. In columns (2) and (4), the sample includes only regions in the South (former Kingdom of Two Sicilies). Each regression controls for the emigration rate and an indicator variable for Southern regions, both interacted with a post-1921 indicator. Robust standard errors are reported in parentheses.

***: $p < 0.01$, **: $p < 0.05$, *: $p < 0.10$

TABLE 4. EXPOSURE TO THE US QUOTA ACTS AND CAPITAL INVESTMENT

Notes. This Table reports the estimated effect of exposure to the US Quota Acts on capital investment. The unit of observation is a province observed at a census-decade frequency between 1911 and 1936. The dependent variables are the number of firms (column 1), the number of firms with at least one engine (column 2), the number of mechanical engines (column 3), the number of electrical engines (column 4), the horsepower generated by mechanical (column 5) and electrical (column 6) engines. In Panel A, the treatment is an interaction between a post-Quota (1921) indicator variable and a dummy for districts with above-median exposure to the Quota Acts (measured as the ratio between US and overall emigrants). In Panel B, the treatment substitutes measured Quota exposure with the shift-share instrument. Each regression controls for the emigration rate and an indicator variable for Southern regions, both interacted with a post-1921 indicator. Regressions include province and decade-fixed effects. Robust standard errors are reported in parentheses.

***: $p < 0.01$, **: $p < 0.05$, *: $p < 0.10$

TABLE 5. EXPOSURE TO THE US QUOTA ACTS AND MANUFACTURING AND AGRICULTURE EMPLOYMENT

Notes. This Table reports the estimated effect of exposure to the US Quota Acts on manufacturing (Panel A) and agriculture (Panel B) employment. The unit of observation is a district observed at a census-decade frequency between 1881 and 1936. In columns (1–2) and (5–6), the treatment is an interaction between a post-Quota (1921) indicator variable the Quota Exposure metric. In columns (3–4), we interact the post-Quota indicator with a dummy returning value one if district-level exposure to the Quota Acts (measured as the ratio between US and overall emigrants) is above the median, and zero otherwise. Columns (7–8) substitute measured Quota exposure with the shift-share instrument. Each regression controls for the emigration rate and an indicator variable for Southern regions, both interacted with a post-1921 indicator. Robust standard errors are reported in parentheses.

***: $p < 0.01$, **: $p < 0.05$, *: $p < 0.10$

Figures

FIGURE 1. INTERNATIONAL MIGRANTS, 1880–1930

Notes. This figure reports the yearly outflow of international migrants from Italy between 1880 and 1930. Data are digitized from the *Annuario statistico dell'emigrazione italiana dal 1876 al 1925: con notizie sull'emigrazione negli anni 1869-1875* edited by the Italian Statistical Office (1926). The blue line reports the overall number of international migrants; the red line reports the number of migrants to the United States, the single most important destination country over this period; the gray line reports emigrants to every other country. The shaded gray area marks the 1914–1918 war years; the dashed vertical black lines mark the 1921 and 1924 Emergency and (Johnson-Reed) Immigration Quota Acts, respectively.

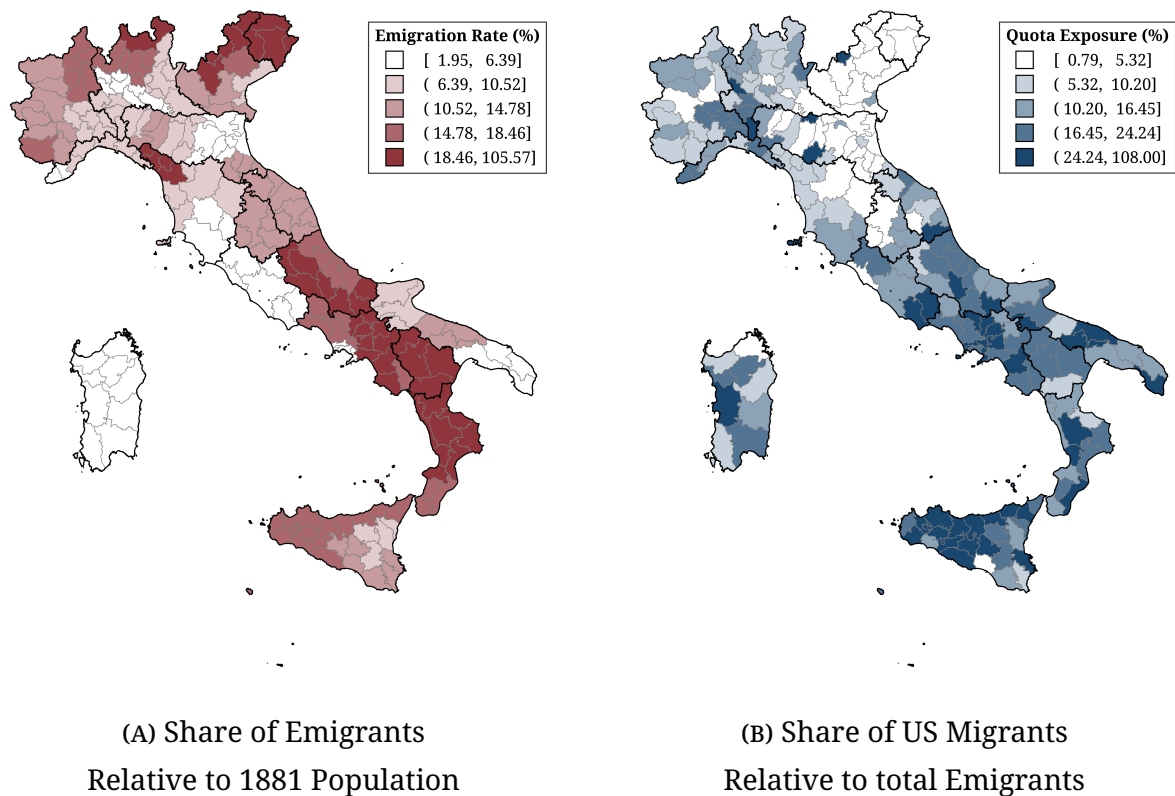

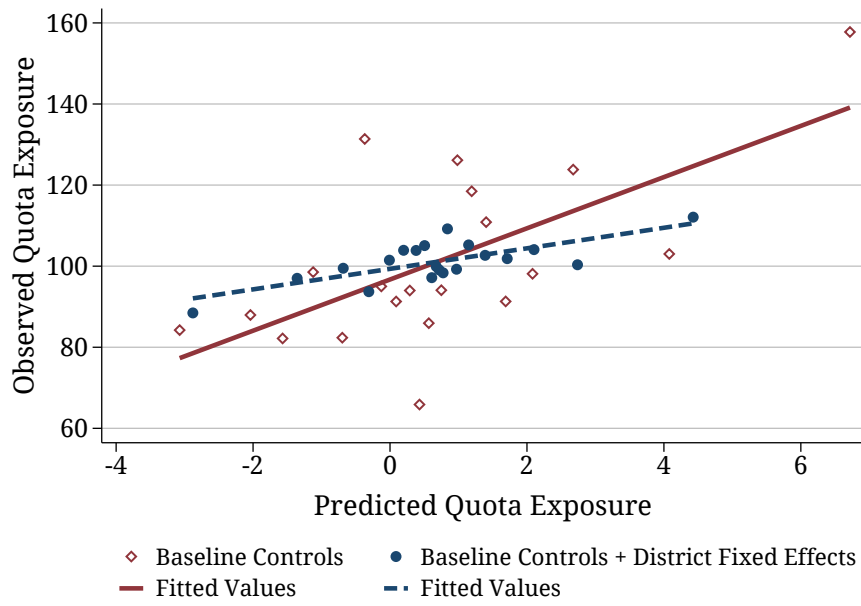

FIGURE 2. SPATIAL DISTRIBUTION OF INTERNATIONAL EMIGRATION, 1892–1925

Notes. These figures report the spatial distribution of the emigration rate (Figure 2a) and of quota exposure (Figure 2b) across districts. In each map, the unit of observation is a district. Black lines superimpose region boundaries. The geography is at 1921 borders. We exclude Trentino-Alto Adige, Venezia-Giulia, Istria, and Dalmatia because districts in those areas are acquired after the Treaty of Versailles (1918). Panel 2a reports the share of international emigrants relative to the district population in 1881. This is computed from province-level data using district-level population, assuming no within-province variation in emigration rates. Panel 2b reports the share of migrants to the United States relative to the number of international migrants. Data refer to the period 1892–1925 and are collapsed at the district level for visualization.

(A) Panel Correlation

(B) Cross-Sectional Correlation

FIGURE 3. FIRST-STAGE CORRELATION BETWEEN MEASURED AND PREDICTED QUOTA EXPOSURE

Notes. These figures report binned scatterplot between actual quota exposure and the shift-share instrument. In Panel 3a, districts are observed yearly between 1900 and 1917. Red dots report the baseline correlation controlling for year-fixed effects and the emigration rate; the blue dots add district-level fixed effects. In Panel 3b, both variables are collapsed at the district level so that each district is observed once. This reflects the treatment variation used in the difference-in-differences analysis. Red dots report the baseline correlation controlling for the emigration rate; the blue dots add region-fixed effects.

FIGURE 4. EFFECT OF EXPOSURE TO THE US QUOTA ACTS ON POPULATION

Notes. These figures report the estimated effect of district-level exposure to the US Quota Acts on population. The unit of observation is a district observed at a census-decade frequency between 1881 and 1936. The outcome variable is population. The treatment is an indicator returning value one if district-level exposure to the Quota Acts (measured as the ratio between US and overall emigrants) is above the median and zero otherwise. Each regression includes district and decade-fixed effects and controls for the emigration rate, and an indicator variable for Southern regions, both interacted with a post-1921 indicator. The bands report 95% confidence intervals from robust standard errors.

(A) Firms

(B) Firms with an Engine

(C) Mechanical Engines

(D) Electrical Engines

(E) Mechanical Horsepower

(F) Electrical Horsepower

FIGURE 5. EFFECT OF EXPOSURE TO THE US QUOTA ACTS ON CAPITAL INVESTMENT

Notes. These figures report the estimated effect of exposure to the US Quota Acts on capital investment over time. The unit of observation is a province observed at a census-decade frequency between 1911 and 1936. The outcome variables are firms (panel 5a), firms with an engine (panel 5b), mechanical (panel 5c) and electrical (panel 5d) engines, mechanical (panel 5e) and electrical (panel 5f) horsepower. The treatment is an indicator returning value one if exposure to the Quota Acts is above the median and zero otherwise. Each regression includes province and decade-fixed effects and controls for the emigration rate and an indicator variable for Southern regions, both interacted with a post-1921 indicator. Bands report 95% confidence intervals from robust standard errors.

(A) Manufacture Employment

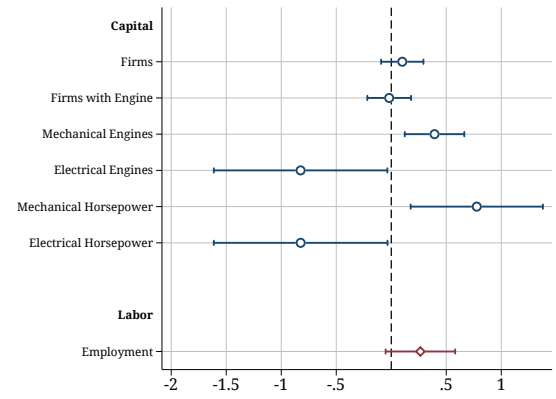

(B) Agriculture Employment

FIGURE 6. EFFECT OF EXPOSURE TO THE US QUOTA ACTS ON EMPLOYMENT BY SECTOR

Notes. These figures report the estimated effect of district-level exposure to the US Quota Acts on manufacturing (Panel 6a) and agriculture (Panel 6b) employment over time. Both outcomes are normalized by the 1881 district population. The unit of observation is a district observed at a census-decade frequency between 1881 and 1936. In panel 6a, the outcome variable is manufacturing employment; in panel 6b, the outcome variable is agriculture employment. The treatment is an indicator returning value one if district-level exposure to the Quota Acts (measured as the ratio between US and overall emigrants) is above the median and zero otherwise. Each regression includes district and decade-fixed effects and controls for the emigration rate, and an indicator variable for Southern regions, both interacted with a post-1921 indicator. The bands report 95% confidence intervals from robust standard errors.

(F) Textiles

FIGURE 7. EFFECT OF EXPOSURE TO THE US QUOTA ACTS ON CAPITAL AND EMPLOYMENT BY SECTOR

Notes. These figures report the estimated effect of exposure to the US Quota Acts on capital and employment by sector over time. The unit of observation is a district observed at a census-decade frequency between 1901 and 1936. Each panel reports the results for a specific manufacturing sector. The outcome variables are listed by row. The treatment is an indicator returning value one if exposure to the Quota Acts is above the median and zero otherwise. Each regression includes district and decade-fixed effects and controls for the emigration rate and an indicator variable for Southern regions, both interacted with a post-1921 indicator. Bands report 90% confidence intervals from robust standard errors.

Emigration Restrictions and Economics Development

Evidence from the Italian Mass Migration to the United States, 1892–1936

Davide M. Coluccia & Lorenzo Spadavecchia

October, 2023

A Data Appendix

A.1 Data Sources

This section lists the sources, methodology, and coverage of the data that we assemble. We defer a more detailed description of the emigration data to section A.3. Table A.1 summarizes the content of this section.

Population Censuses. We extract information from population censuses in 1881, 1901, 1911, 1921, 1931, and 1936. No census was taken in 1891. We digitize district-level information on the number of people employed in all major sectors in 1881–1921 censuses. The same information is available at the municipality level for 1931 and 1936. Hence we aggregate it at the district level. To assign municipalities to districts, we geo-code each municipality and overlay the coordinates to the 1921 district shape file. From population censuses, we also extract information on employment by industry: this is available by districts until 1921 but only by provinces in 1931 and 1936. We thus aggregate industry employment to provinces. Population data have been tabulated by ISTAT for each municipality. We aggregate them at the district and province levels. We also code two types of urbanization variables: the share of the population living in districts with at least k -thousand municipalities and the share of municipalities with at least k -thousand inhabitants. The ISTAT population tables report information on the area, altitude, and access to the sea for each municipality.

Manufacture Censuses. Manufacture censuses were taken in 1911, 1927, and 1937. They report province-level information on the universe of firms. We digitize data on a set of proxies for capital investment: the number of firms, the number of firms with at least one installed engine, the number of installed mechanical and electrical engines, and the number of installed mechanical and electrical horsepower.

World War One Deaths. WW1 deaths are from *cadutigrandeguerra.it*, a dataset maintained by ISTORECO, a branch of the *Associazione Nazionale Partigiani d'Italia* (ANPI). The underlying data were collected by the Fascist regime for propaganda purposes. The honor roll call contains information on 570,355 Italian soldiers who lost their lives during the war. The data appears to be comprehensive since most estimates place the total death toll at 650,000. For each individual, we know the name and surname, the birth year, the municipality of origin—which we map to the municipalities listed in the ISTAT data—the military rank at death, the regiment, when, where, and why they died, and the decoration, if any. Deaths span the war years (1915–1918). We aggregate them at the district and province levels to have a cross-sectional indicator of mortality.

Railway Data. We reconstruct the network of Italian railways between 1839 and 1926 from a volume curated by the Italian Statistical Office and edited in 1927. This is the first paper using these data. The unit of observation in the data is truck lines connecting two stations. We have information on the precise

date when each line opened and the distance it covered, and the name of the station it connected. We geo-code the location of each station and generate a dummy variable that indicates whether a given municipality had at least one station, as well as a count variable returning the number of stations. We also define a variable that returns the number of kilometers that separate every given municipality from the closest transatlantic migration port. Calabrese (2017) suggests that railway access to Genoa, Palermo, or Naples—the only ports with ships sailing toward the United States—was a crucial condition to ignite migration movements. We thus compute the shortest path connecting each municipality with each transatlantic port given the state of the railway network in every given year and take the closest among the three. We aggregate this variable by district and province, taking a population-weighted average of the shortest railway distances to emigration ports.

A.2 Construction of the Sample

All variables that are not computed from geo-coded data are cross-walked to consistent 1921 district and border geographies using the method described by Eckert *et al.* (2020). To do so, we use GIS boundary files publicly provided by ISTAT for each census year. Even though this yields quantitatively minor corrections, it is important to ensure that geographies remain consistent because the Fascist regime undertook an extensive revision of local government divisions, which ultimately abolished districts in 1927.

We forcibly exclude areas that were annexed as a consequence of World War One in 1918—Trento and Trieste, Südtirol, Istria, and Zara—because we do not observe pre-Quota outcomes in those regions.

Unlike for US emigrants, we do not have district-level data on overall emigration. To assign province-level emigration to districts, we assume that emigration rates were constant within each province. We then impute district emigration by multiplying province emigration by the share of inhabitants in each district compared to the province population before the mass migration (in 1881).

We assemble three distinct samples. The first one, which comprises population and employment-by-sector data, is at the district level and covers the years 1881, 1901, 1911, 1921, 1931, and 1936. Agriculture employment is not available in 1931. All data in sample one are either digitized from population censuses or are aggregated from data tabulated by ISTAT. The second sample runs at the province level, covers capital variables, and is available in 1911, 1927, and 1937. Capital variables are retrieved from manufacturing censuses. The third sample runs at the province level, covers employment-by-industry variables, and spans the years 1901, 1911, 1921, 1927, and 1936. For the first three decades, the data are from population censuses; for the latter two, we digitize them from manufacturing censuses.

Since capital variables exhibit substantial kurtosis, we winsorize the top and bottom 5% of their distribution.

A.3 Details on the Emigration Data

In this section, we document in detail the novel emigration data that we collect. The raw data can be found at <https://heritage.statueofliberty.org/>. First, we describe the methodology that we adopt to assemble the data. Second, we show how to validate this dataset with external sources. Last, we present some stylized facts that the new data allow us to document.

This new dataset responds to a key limitation of commonly used US census data (Ruggles *et al.*, 2021). These list the country of origin of immigrants residing in the US, but they do not report where immigrants originated from within their home country. This issue applies to all countries. Hence separate papers developed strategies to reconstruct such information for, among others, Norway (Abramitzky *et al.*, 2014) and England (Coluccia and Dossi, 2023). This is the first paper that looks at Italians, a major country of emigration among the so-called “second-wave” nations.

A.3.1 Methodology

We run queries over a comprehensive set of the most common 20,000 Italian surnames between 1890 and 1930. We collect individual-level information on the name and surname of immigrants, their municipality of origin, their immigration year, and whether they can read or write.

The municipality of origin is recorded consistently only between 1892 and 1924. Names, surnames, and municipalities are frequently coded with spelling errors, possibly because they were recorded by American enumerators. In this paper, we are interested in the municipality of origin of immigrants. We tackle this data quality issue in two steps. First, we pick the 1,000 most common origin municipalities in the data, and we correct eventual coding errors in those manually. We also discard too coarse entries, such as “Italy” or “Sicily.” Then, we geo-code the remaining entries using Google Maps’ auto-correction algorithm. Then, we manually checked that the return geo-coded locations are reliable for a subset of 200 municipalities. The algorithm successfully matches 189 out of 200 municipalities. The remaining 11 are impossible to match even by hand. We assess the plausibility of this matching exercise in section [A.3.2](#).

The municipality of origin is missing for a non-negligible sub-sample of immigrants. In [Figure A.1](#), we report graphical evidence. The top panel reports the absolute number of recorded immigrants (in blue) and those which we match to a municipality. The bottom panel reports the share of immigrants with at least one listed origin (in blue) and the share that we match to a municipality. Throughout the years 1900–1914—the key years of the mass migration and the ones on which we compute our treatment variable—the sample of immigrants with a matched municipality always exceeds 80% of the total records. This share is lower at the beginning of the sample—perhaps because origins started being recorded in 1892—and after World War Two. Municipalities after the 1924 Immigration Act, in particular, were seldom

recorded, but we never use this sample period in this paper.

In the analysis, the dataset is aggregated by district or province depending on the part of the analysis using boundaries in 1921 from historical shape files provided by ISTAT.

A.3.2 Validation

The newly granular nature of the dataset implies that we cannot validate it with existing data at similar levels of aggregation. Our strategy, instead, is to aggregate it at the regional level and compare it with data from official statistics on Italian emigration to the United States collected by the Commissioner General for Emigration. These span the period 1877–1925 and are available by region.

In Table A.2, we report the correlation between the Ellis Island dataset and US emigration as recorded in official statistics. In columns (1–5), we report the correlation between the raw series, while in columns (6–7), we take logs. We find a positive and large unconditional correlation between the two (columns 1 and 6). In particular, Ellis Island migration explains more than 80% of the region-level variation in US emigration as measured in official statistics. This correlation remains conditioning on year (2 and 7), region (3 and 8), and year and region (4 and 9) fixed effects. Importantly it holds within the sub-sample period we use to compute the treatment (5 and 10). Figure A.2 displays the unconditional correlation between the two series (A.2a) and the one absorbing region and year fixed effects (A.2b). These exercises document a positive, large, and statistically significant correlation between the Ellis Island US emigration and data from official statistics. Finally, in Figure A.3, we check that the correlation remains high in each year of the observation sample. Each dot in the figure reports the correlation between the two series in one year between 1892 and 1924. The correlation remains stable, positive, and statistically significant throughout the sample period.

A.3.3 Stylized Facts

Dissecting the specific features of mass emigration to the United States is beyond the scope of this paper. Instead, we present two suggestive facts.

First, in Table A.3, we list the districts that were relatively more exposed to the US migration. In columns (1–3), districts are ranked by the absolute number of emigrants. In columns (4–6), we rank them by the emigration rate, expressed as the ratio between overall US emigrants and the 1921 population. The vast majority of top-ranked districts are located in Southern regions. Emigration rates are higher in Sicily and Campania. The district of Palermo alone accounts for almost 90,000 emigrants out of a population of 850,000.

We then provide evidence supporting the S-hypothesis advanced by Gould (1980) and recently analyzed by Spitzer and Zimran (2023). This maintains that local out-migration patterns followed a logistic-

type dynamic, with initially low uptake, large increases in a relatively short time period, and subsequent plateau. Gould (1980) connects these dynamics to information diffusion within the population. To test this hypothesis, we mark the beginning of the mass migration in each district when the US emigration rate exceeded 0.1‰. This generates a setting akin to a staggered treatment roll-out. We then use the method of Borusyak *et al.* (2022) to estimate the dynamics of US out-migration. Importantly, this approach ensures that we compare emigration districts with areas where the migration had not already begun. We find that emigration followed Gould’s S-shaped pattern as documented by Spitzer and Zimran (2023). We interpret this finding as additional evidence supporting the quality of the underlying data.

TABLE A.2. CORRELATION BETWEEN ELLIS ISLAND AND OFFICIAL STATISTICS US EMIGRATION

Notes. This Table compares the number of US emigrants recorded in Italian official statistics with data from the Ellis Island Foundation dataset. The unit of observation is a region at a yearly frequency. The sample period spans 1892 to 1925. In columns (1–5), the dependent and independent variables are the number of emigrants recorded in official statistics and at Ellis Island, respectively. In columns (6–10), both variables are taken as log(1+). Columns (1) and (6) display the unconditional correlation; in columns (2) and (7), (3) and (8), and (4) and (9), we include year, region, and year and region fixed effects. In columns (5) and (10), we restrict the observation sample to the years 1900–1914, which is the period that we use to construct the baseline treatment in the analysis. Standard errors are always clustered at the region level and are displayed in parentheses.

TABLE A.3. MOST COMMON EMIGRATION DISTRICTS

Notes. This Table reports the districts with the largest number of US emigrants (columns 1–3) and US emigration rates relative to the 1921 population (columns 4–6). We list the top 30 origin districts in each category. Emigration rates are expressed in per-thousand units.

A.5 Figures

(A) Number of US Immigrants

(B) Share of US Immigrants

FIGURE A.1. MISSING ORIGIN IN THE ELLIS ISLAND DATASET

Notes. This Figure reports data on the missing municipality of origin in the Ellis Island dataset. In Panel A.1a, we display the absolute number of immigrants (in blue) and immigrants for whom we can assign a municipality of origin (in red). In Panel A.1b, we display the share of immigrants with at least one listed place of origin (in blue) and those for whom we can assign the listed origin to a municipality.

(A) Unconditional Correlation

(B) Conditional Correlation

FIGURE A.2. CORRELATION BETWEEN OFFICIAL STATISTICS AND ELLIS ISLAND US EMIGRATION

Notes. This Figure reports the correlation between the number of US emigrants recorded in the Italian official statistics and the number of Italian immigrants recorded in the Ellis Island dataset. The unit of observation is a region at a yearly frequency between 1892 and 1925. In Panel A.2a, we report the unconditional correlation. Panel A.2b displays the correlation between the variables after residualizing region and year-fixed effects. Both graphs report the fitted values of a linear regression between the variables.

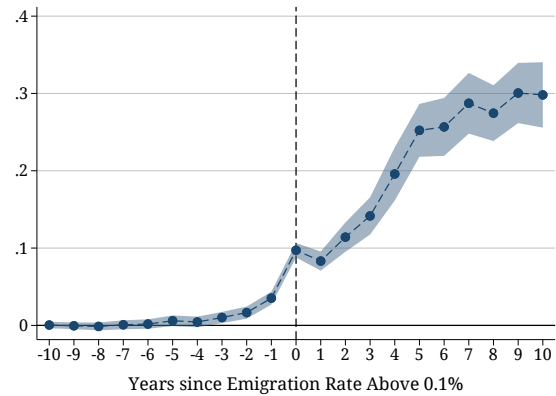

FIGURE A.3. YEAR-BY-YEAR CORRELATION BETWEEN ELLIS ISLAND AND OFFICIAL STATISTICS US EMI-GRANTS

Notes. This Figure reports the correlation between the number of US emigrants recorded in the Italian official statistics and the number of Italian immigrants recorded in the Ellis Island dataset. Each dot reports the correlation between the two variables in one specific year between 1892 and 1925. In each dot, the unit of observation is a region. Both variables are standardized to have zero mean and unitary standard deviation in each year for readability. The bars report 95% confidence intervals from standard errors clustered at the regional level. The grey area marks the years that we used to construct the baseline treatment of exposure to the Quota Acts.

(A) Unconditional Emigration

(B) Emigration Net of Fixed Effects

FIGURE A.4. TESTING THE S-SHAPED HYPOTHESIS

Notes. These figure test the S-shape emigration hypothesis of Gould (1980). The dependent variable is US emigration, observed at the district level every year between 1892 and 1924. For each district, we define an indicator variable that returns the number of years since the ratio between US emigrants and population in 1921 exceeds 0.1%. We report the estimated difference-in-differences coefficients obtained using the method of Borusyak *et al.* (2022) around this threshold. Panel A.4a does not include any fixed effect in the regression; in Panel A.4b, we include district and year fixed effects. Standard errors are clustered at the district level; bands report 99% confidence intervals.

TABLE B.1. FIRST-STAGE REGRESSIONS

Notes. This Table reports the correlation between the US emigration rate and the predicted US emigration rate constructed from equation (4). The units of observation are districts. In columns (1–4), each district is observed yearly between 1900 and 1914. In columns (5–8), each district is observed once, and the outcome and the dependent variables are aggregated over time. Columns (1) and (5) report the unconditional correlations; in columns (2), (3), and (4), we additionally include region, district, and region-by-year fixed effects. In columns (6), (7), and (8), we include the baseline controls, region, and province fixed effects. Robust standard errors are displayed in parentheses.

TABLE B.2. REGIONAL US AND OVERALL EMIGRATION, 1876–1925

Notes. This Table reports regional emigration towards the US and total emigration from 1876 to 1925. Figures are in thousands. Column (11) indicates the percentage of total emigrants towards US relative to all emigrants from the given region in the whole period 1876-1925.

TABLE B.3. INTERNAL AND INTERNATIONAL MIGRATIONS, 1921–1931

Notes. This Table reports internal migration and out-migration flows over the period 1921-1931. Column (1) reports the population in 1881. Column (2) is the net internal migrant flow. To compute net internal migration flows, we take the difference in the outflow of people leaving a given region and the inflow of people arriving in that region during the decade 1921-1931. Since Census data only report the stock of people born in a given region living in another region in 1921 and 1931, to compute the outflow of people leaving a region during that decade, we take the difference across years of the total number of people born in that region and living in any other Italian region. Similarly, to compute the inflow of people arriving in a region during that decade, we take the difference across years of the total number living in that region who were born in any other Italian region. Positive (negative) figures imply a net population loss (gain) due to internal migrations. Column (3) reports the number of international emigrants. Figures are in thousands. Columns (4–5) report net internal and international migration figures relative to the 1881 population. Figures are in percentage terms.

TABLE C.1. EXPOSURE TO THE US QUOTA ACTS AND POPULATION

Notes. This Table reports the estimated effect of district-level exposure to the US Quota Acts on population. The unit of observation is a district observed at a census-decade frequency between 1881 and 1936. Each column represent the estimates of a regression where the treatment is an interaction between a post-Quota (1921) indicator variable and the district-level exposure to the Quota Acts (measured as the log of the ratio between US and overall emigrants). We use five different measures of Quota Exposure, constructed using different weighting of the number of emigrants to the US or computing the number of US emigrants over different time spans. In column 1 and 2 we respectively assign a higher weight to emigrants departed closer to the Quota Acts date and much earlier in time: for both measures we adopt an exponential weighting of factor 0.9. In columns 3, 4 and 5 we respectively construct the Quota Exposure using the number emigrants to the US departed, respectively, between 1900 and 1924, between 1900 and 1920, and between 1900 and 1914. Each regression controls for the emigration rate and an indicator variable for Southern regions, both interacted with a post-1921 indicator. In columns 6-10 we replicate the analysis substituting the measured Quota exposure with the shift-share instrument. Robust standard errors are reported in parentheses.

TABLE C.2. EXPOSURE TO THE US QUOTA ACTS AND CAPITAL INVESTMENT

Notes. This Table reports the estimated effect of exposure to the US Quota Acts on capital investment. The unit of observation is a province observed at a census-decade frequency between 1911 and 1936. The dependent variables are the number of firms (column 1), the number of firms with at least one engine (column 2), the number of mechanical engines (column 3), the number of electrical engines (column 4), the horsepower generated by mechanical (column 5) and electrical (column 6) engines. The treatment is an interaction between a post-Quota (1921) indicator variable and a dummy for districts with above-median exposure to the Quota Acts (measured as the ratio between US and overall emigrants). In the five panels we use different measures of Quota Exposure, constructed using different values for the number of US emigrants. In Panel A and B we respectively assign a higher weight to emigrants departed closer to the Quota Acts date and much earlier in time: for both measures we adopt an exponential weighting of factor 0.9. In Panel C, D and E we respectively construct the Quota Exposure using the number of emigrants to the US departed, respectively, between 1900 and 1924, between 1900 and 1920, and between 1900 and 1914. Each regression controls for the emigration rate and an indicator variable for Southern regions, both interacted with a post-1921 indicator. In Panel F, we substitute our measured quota exposure with the shift share instrument: we use an indicator variable for province with above-median (predicted) exposure to the Quota Acts. We report the results in Panel F only, since the indicator variable takes the same value, regardless of the way we construct it using different sample periods. Robust standard errors are reported in parentheses.

TABLE C.3. EXPOSURE TO THE US QUOTA ACTS AND MANUFACTURE EMPLOYMENT

Notes. This Table reports the estimated effect of exposure to the US Quota Acts on manufacturing employment. The unit of observation is a district observed at a census-decade frequency between 1881 and 1936. Each column represent the estimates of a regression where the treatment is an interaction between a post-Quota (1921) indicator variable and the district-level exposure to the Quota Acts (measured as the log of the ratio between US and overall emigrants). We use five different measures of Quota Exposure, constructed using different weighting of the number of emigrants to the US or computing the number of US emigrants over different time spans. In column 1 and 2 we respectively assign a higher weight to emigrants departed closer to the Quota Acts date and much earlier in time: for both measures we adopt an exponential weighting of factor 0.9. In columns 3, 4 and 5 we respectively construct the Quota Exposure using the number emigrants to the US departed, respectively, between 1900 and 1924, between 1900 and 1920, and between 1900 and 1914. Each regression controls for the emigration rate and an indicator variable for Southern regions, both interacted with a post-1921 indicator. In columns 6-10 we replicate the analysis substituting the measured Quota exposure with the shift-share instrument. Robust standard errors are reported in parentheses.

TABLE C.4. EXPOSURE TO THE QUOTA ACTS AND AGRICULTURE EMPLOYMENT

Notes. This Table reports the estimated effect of exposure to the US Quota Acts on agriculture employment. The unit of observation is a district observed at a census-decade frequency between 1881 and 1936. Each column represent the estimates of a regression where the treatment is an interaction between a post-Quota (1921) indicator variable and the district-level exposure to the Quota Acts (measured as the log of the ratio between US and overall emigrants). We use five different measures of Quota Exposure, constructed using different weighting of the number of emigrants to the US or computing the number of US emigrants over different time spans. In column 1 and 2 we respectively assign a higher weight to emigrants departed closer to the Quota Acts date and much earlier in time: for both measures we adopt an exponential weighting of factor 0.9. In columns 3, 4 and 5 we respectively construct the Quota Exposure using the number emigrants to the US departed, respectively, between 1900 and 1924, between 1900 and 1920 and between 1900 and 1914. Each regression controls for the emigration rate and an indicator variable for Southern regions, both interacted with a post-1921 indicator. In columns 6-10 we replicate the analysis substituting the measured Quota exposure with the shift-share instrument. Robust standard errors are reported in parentheses.

TABLE C.5. EXPOSURE TO THE US QUOTA ACTS AND POPULATION

Notes. This Table reports the estimated effect of district-level exposure to the US Quota Acts on population. We replicate the results obtained in column 6 of Table 3. In each column we control for the interaction between the post-Quota indicator variable and a district- or country-specific variable. In column 1 we use the district's literacy rate in 1901; in column 2 the urbanization rate in 1901, measured as the share of people living in towns with more than 10'000 inhabitants in the district; in column 3 the altitude at which the district is located; in column 4 an indicator variable specifying whether the district was connected to the railway network before 1901; in column 5 district's number of deaths caused by WW1, measured as share of the district's population. In column 6 we use the US GDP growth: being this a time-varying variable common to all districts, we further interact it with the district's Quota Exposure. Each regression controls for the emigration rate and an indicator variable for Southern regions, both interacted with a post-1921 indicator. In columns 7-12 we replicate the analysis substituting the measured Quota exposure with the shift-share instrument. Robust standard errors are reported in parentheses.

C.2 Figures

FIGURE C.1. ALTERNATIVE STANDARD ERRORS: DISTRICT-LEVEL LINEAR PROBABILITY MODELS

Notes. This Figure reports alternative estimators of the standard errors in the baseline district-level regressions. The unit of observation is a district, at a decade frequency between 1881 and 1936. The dependent variable is population (Panel C.1a), manufacturing employment (Panel C.1b), and agriculture employment (Panel C.1c). Regressions are estimated through OLS and include district and decade-fixed effects. Bands report 90% confidence intervals.

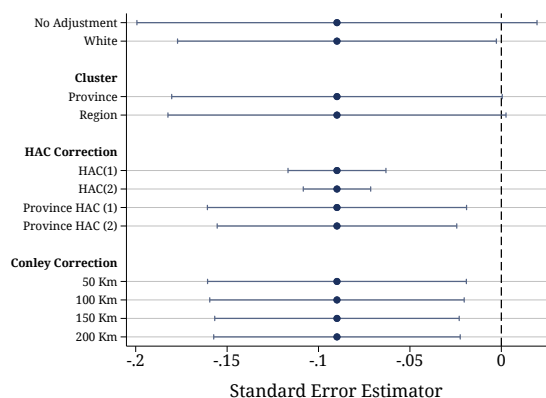

FIGURE C.2. EXCLUDING ONE REGION AT THE TIME: DISTRICT-LEVEL LINEAR PROBABILITY MODELS

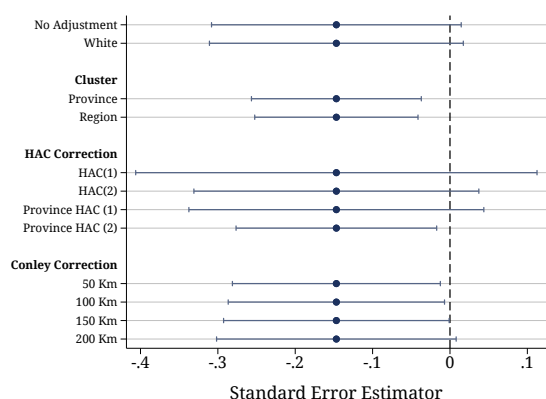

Notes. This Figure reports the estimates of the baseline district-level regressions when excluding one region. The unit of observation is a district, at a decade frequency between 1881 and 1936. The dependent variable is population (Panel C.2a), manufacturing employment (Panel C.2b), and agriculture employment (Panel C.2c). Regressions are estimated through Poisson regression and include district and province-decade fixed effects: refer to column 6 of Table 3 and 5. The left axis indicates the excluded region. Bands report 95% confidence intervals.

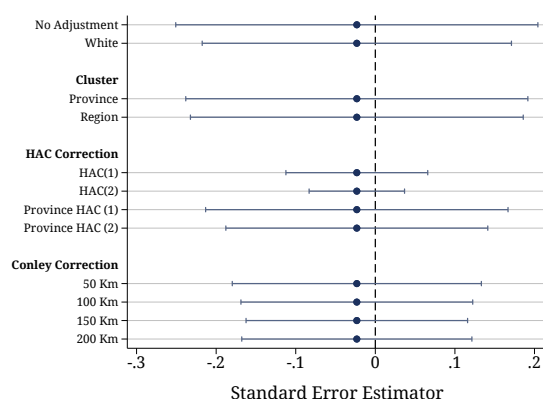

(A) Firms

(B) Firms with Engine

(C) Mechanical Engines

FIGURE C.3. ALTERNATIVE STANDARD ERRORS: PROVINCE-LEVEL LINEAR PROBABILITY MODELS

Notes. This Figure reports alternative estimators of the standard errors in the baseline province-level regressions. The unit of observation is a province, at a decade frequency between 1911 and 1937. Regressions are estimated through OLS on the $\log(1 + \cdot)$ -transformed variable and include province and decade-fixed effects. Bands report 90% confidence intervals.

(A) Firms

(B) Firms with Engine

(C) Mechanical Engines

(D) Electrical Engines

(E) Mechanical Horsepower

(F) Electrical Horsepower

FIGURE C.4. EXCLUDING ONE REGION AT THE TIME: PROVINCE-LEVEL LINEAR PROBABILITY MODELS

Notes. This Figure reports the estimates of the baseline province-level regressions when excluding one region. The unit of observation is a province, at a decade frequency between 1911 and 1937. Regressions are estimated through a double-difference (DiD) Poisson regression and include province and decade-fixed effects: refer to Panel A of Table 4. The left axis indicates the excluded region. Bands report 95% confidence intervals.

D Theoretical Framework

In this section we develop a simple framework to rationalize our main findings in the context of labor-saving technical change theory. Proofs and further analytical insights on the baseline environment can be found in section D.3.

D.1 Theoretical Framework

In this section we develop a simple analytical framework inspired to Zeira (1998) and San (2023) to clarify the empirical implications of directed technical change and adoption theory. The core assumption we make is that capital goods—hereafter, machines—substitute labor as a production input. We thus implicitly restrict technological progress to be labor-saving, as in Acemoglu (2002, 2007). The decision of the firm to adopt productivity-enhancing machines will depend on their price relative to the cost of labor. In the equilibrium a labor supply shock—such as the one induced by IRPs—dampens the incentive to adopt machines because it pushes down the wage, hence prompting firms to substitute capital with labor.

Consider a closed economy with one consumption good, and a representative household supplying labor. The consumption good is produced by a continuum of tasks $j \in [0, 1]$. Each task can be performed with either labor or machines. The amount of machines in task j is denoted by $x(j)$, whereas the amount of labor employed is $e(j)$. Note that each task can be fulfilled with either machines or labor, but not both. This is intended to model in a stylized manner labor-saving machines. To simplify the analysis and following ? we assume that machines fully depreciate at the end of the period, hence the model is essentially static.

The final consumption good is produced by identical perfectly competitive firms with the following production function:

$$Y = A \left[\int_0^\iota m x(j)^\alpha dj + \int_\iota^1 e(j)^\alpha dj \right] \quad (\text{D.1})$$

where A is a technology parameter, m is the relative productivity of machines and $\alpha \in (0, 1)$ is a production parameter. We assume $m \in (0, 1)$ following San (2023), and restrict machines to be equally productive across tasks j . The choice variable $\iota \in [0, 1]$ denotes *industrialization* defined as the share of automatized tasks, which are those fulfilled by machines. We assume that tasks are ordered by degree of complexity. Because the marginal cost of producing machines—which we define below—is increasing in complexity, the price of machines is non-decreasing in j . It is therefore without loss of generality to assume that the first ι tasks are automatized. This is because the final good producer will first automatize tasks whose machine costs the least, since the relative productivity of machines is constant across tasks. We assume that there is a fixed stock of labor $L > 0$ which is supplied inelastically by the household.

The problem of the representative final good producer is therefore to choose the industrialization

level ι , and input quantities $x(j)$ and $e(j)$ for each task, to maximize profits

$$\max_{\iota, \{x(j), e(j)\}_{j \in [0,1]}} Y - \int_0^\iota p(j)x(j) dj - w \int_\iota^1 e(j) dj \quad (\text{D.2})$$

where $p(j)$ is the price of a machine for task j , w is the nominal wage, subject to the technology constraint (D.1). Note that the price of the consumption good is implicitly normalized to one. In section D.3, we formally show that the demand schedules for machines and labor are given by the following demand schedules:

$$x(j) = p(j)^{-\frac{1}{1-\alpha}} (\alpha A m)^{\frac{1}{1-\alpha}} \quad \forall j \in [0, \iota] \quad (\text{D.3a})$$

$$e(j) = w^{-\frac{1}{1-\alpha}} (\alpha A)^{\frac{1}{1-\alpha}} \quad \forall j \in [\iota, 1] \quad (\text{D.3b})$$

Combining (D.3a)-(D.3b) with the first order condition for the industrialization rate, it follows that in the equilibrium ι^* is pinned down by the following:

$$m = \left[\frac{p(\iota^*)}{w} \right]^\alpha \quad (\text{D.4})$$

The economic intuition behind condition (D.4) is that at the marginal task, *i.e.* the last automatized task, the price of the machine fulfilling the task must be equal to the cost of labor, adjusted by the technology parameter and the relative productivity of machines.

Each machine is produced by a monopolist, following Zeira (1998). The machine producer will seek to set the monopoly price which maximizes its profits subject to demand for machines (D.3a). We assume that the marginal cost of machines $\psi(\cdot)$ is increasing in the complexity of tasks, *i.e.* $\psi'(\cdot) > 0$. Moreover, we assume that the marginal cost function satisfies basic Inada conditions.²⁰ This is intended to capture the idea that machines substituting low-skill tasks are not as expensive as those replacing tasks on the right side of the skill distribution of workers. The problem of the machine producer is therefore

$$\max_{p(j)} [p(j) - \psi(j)] x(j) \quad (\text{D.5})$$

subject to (D.3a). In section D.3, we show that the first-order conditions imply

$$p(j) = \min \left\{ mw, \frac{\psi(j)}{\alpha} \right\} \quad (\text{D.6})$$

where the minimum descends from the observation that because each task can be performed by labor as well as by machines, setting a price greater than the productivity-adjusted wage simply pushes the final goods producer not to automatize the task. We now obtain two technical results to ensure the existence and uniqueness of the equilibrium. The formal definition of the competitive equilibrium in this economy, as well as the proofs of all lemmas and propositions, can be found in section D.3.

²⁰In this setting, this simply boils down to $\lim_{j \uparrow 1} \psi(j) = +\infty$ and $\lim_{j \downarrow 0} \psi(j) = 0$. The economic intuition behind these is that it is never profitable for the representative firm to automatize all tasks. Similarly, there is always at least one task that is automatized. Note that while these assumptions are sufficient for the existence of an equilibrium, they are not necessary.

Lemma D.1. *In the equilibrium, the marginal task ι^* is such that $p(\iota^*) = \psi(\iota^*)/\alpha = wm^{1/\alpha}$.*

Combining this result with the equilibrium conditions of the final goods producer, we derive the following strong existence result.

Proposition D.1. *There exists one and only one $\iota^* \in [0, 1]$ which solves the problem of the final good producer (D.3a)-(D.3b)-(D.4) as well as the problem of the machine producers (D.6) and verifies labor market clearing. In particular, the equilibrium industrialization ι^* is the solution to the following:*

$$\psi(\iota^*) = L^{\alpha-1}(1 - \iota^*)^{1-\alpha}\alpha^2 Am^{1/\alpha}.$$

This concludes our analytical characterization of the environment. We now exploit the model to deliver a number of testable predictions which will guide our empirical analysis.

D.2 Empirical Testable Implications

Having established the existence of the equilibrium, we can now derive two key empirical implications of this directed technical adoption setting. First, note that Lemma D.1 conveys the basic intuition of the model. In particular, we have $\psi(\iota^*) = \alpha m^{1/\alpha} w$, hence an increase in the nominal wage induces industrialization to rise because $\psi'(\cdot) > 0$ by assumption. The economic intuition behind this result is that if the cost of labor increases, then the final good producer will seek to automatize more tasks in order to avoid paying the increase in the wage. This is summarized in the following implication statement.

Implication D.1. Following an exogenous increase (resp. decrease) in the nominal wage w , the share of tasks performed by machines ι^* increases (resp. decreases).

A similar comparative static result follows considering an increase in the labor stock. To see it, notice that because the nominal wage is invariant across tasks, from (D.3b) and labor market clearing the total labor stock L is evenly allocated across the $(1 - \iota^*)$ non-automated tasks. Using this insight, we obtain the following empirical prediction.

Implication D.2. Following an exogenous increase (resp. decrease) in the labor supply stock L , the share of tasks performed by machines ι^* decreases (resp. increases).

This is the key implication of the model that we test in the paper. In our setting, we provide evidence that immigration restriction policies induce positive labor supply shocks, hence increasing the labor stock. We show that firms operating in districts that were more exposed to the Quota Acts decreased investment in machinery—section IV.3—and increased employment—section IV.4. These findings are

fully in line with the empirical predictions D.2 of the model and hence provide evidence in favor of labor-saving directed technical adoption.

Implications D.1-D.2 are tested using aggregate data on manufacturing employment and investment in physical capital. We provide some results at a more disaggregated sector level. We refer to relatively backward and modern sectors as respectively “First” and “Second Industrial Revolution” sectors. For concreteness, the former comprises textiles and construction whereas the latter mainly refers to the chemical and metalworking industries. To capture this difference in the model, we assume that machines in the relatively modern sector are more productive than those in the relatively backward one. The following result holds.

Implication D.3. Let M and L respectively denote a modern and a backward sector which differ by the productivity of machines $1 > m_M > m_B > 0$. Then, following a positive (resp. negative) labor supply shock, the share of industrialized tasks if $m = m_B$ decreases (resp. increases) more than if $m = m_M$.

We test this prediction using data on employment and technology adoption at the sector level of aggregation. We find that in the First Industrial Revolution sectors investment in capital goods and employment respectively decreased and increased considerably more than in Second Industrial Revolution industries. This finding is fully consistent with prediction D.3.

D.3 Proofs of Analytical Results

Solution of the problem of the final good producer. Plugging the technology constraint into problem (D.2), the problem of the final good producer reads out as follows:

$$\max_{\iota, \{x(j), e(j)\}_{j \in [0,1]}} A \left[\int_0^\iota m x(j)^\alpha dj + \int_\iota^1 e(j)^\alpha dj \right] - \int_0^\iota p(j)x(j) dj - w \int_\iota^1 e(j) dj$$

The—necessary and sufficient—first-order conditions with respect to labor and capital in the generic task j are

$$\begin{aligned} x(j) &= p(j)^{-\frac{1}{1-\alpha}} (\alpha A m)^\frac{1}{\alpha} \quad \forall j \in [0, \iota] \\ e(j) &= w^{-\frac{1}{1-\alpha}} (\alpha A)^\frac{1}{\alpha} \quad \forall j \in [\iota, 1] \end{aligned}$$

To obtain the first-order condition for the optimal industrialization rate, apply the Leibniz integral rule with respect to ι to get:

$$x(\iota^*) [m x(\iota^*)^{\alpha-1} - p(\iota^*)] = e(\iota^*) [e(\iota^*)^{\alpha-1} - w]$$

Plugging (D.3a)-(D.3b) into the expression above we get $m = (p(\iota^*)/w)^\alpha$. □

Solution of the problem of the monopolist. The solution is trivial upon plugging (D.3a) into the objective function (D.5). □

Proof of Lemma D.1. From (D.6) and (D.4), it is

$$p(\iota^*) = \min \left\{ \frac{\psi(\iota^*)}{\alpha}, mw \right\}$$

$$p(\iota^*) = m^{1/\alpha} w$$

Hence, we have

$$m = \left[\frac{\min \left\{ \frac{\psi(\iota^*)}{\alpha}, mw \right\}}{w} \right]^\alpha$$

We can distinguish two cases. Assume $mw \leq \psi(\iota^*)/\alpha$. This implies that $m = m^\alpha$, which is only verified if $m = 1$ or $m = 0$. Since by assumption $m \in (0, 1)$, this can never hold. We are left with the case $mw > \psi(\iota^*)/\alpha$. We show that this is consistent with all the parameter restrictions. Note first that since $m \in (0, 1)$, it must be $\psi(\iota^*)/\alpha < w$, since otherwise it would be $m \geq 1$. We therefore have $\psi(\iota^*)/\alpha < w$ and $\psi(\iota^*)/\alpha < mw$. Because $m < 1$, the only binding constraint is $\psi(\iota^*)/\alpha < mw$. It is

$$m = \left[\frac{\psi(\iota^*)}{\alpha} \cdot \frac{1}{w} \right]^\alpha$$

which implies $\psi(\iota^*)/\alpha = wm^{1/\alpha}$. Because $m \in (0, 1)$, $m^{1/\alpha} < m$ since $\alpha \in (0, 1)$, and therefore $\psi(\iota^*)/\alpha = wm^{1/\alpha} < wm$. This implies that the solution is acceptable. Hence, $p(\iota^*) = \psi(\iota^*)/\alpha$ and this concludes the proof. \square

Proof of Proposition D.1. Because $w(j) = w$ for all $j \in [0, 1]$, from (D.3b) we get that $e(j)$ does not depend on j and:

$$e(j) = e = w^{-\frac{1}{1-\alpha}} (\alpha A)^{\frac{1}{1-\alpha}} = \frac{L}{1 - \iota^*}$$

where the last equality holds by labor market clearing, which requires $(1 - \iota^*)e = L$. From Lemma D.1, it is $w = \psi(\iota^*)/(\alpha m^{1/\alpha})$. Plugging this into the previous equation we get

$$\left(\frac{\psi(\iota^*)}{\alpha m^{1/\alpha}} \right)^{-\frac{1}{1-\alpha}} (\alpha \beta)^{\frac{1}{1-\alpha}} = \frac{L}{1 - \iota^*}$$

$$\frac{\psi(\iota^*)}{\alpha m^{1/\alpha}} (\alpha \beta)^{-1} = \left(\frac{L}{1 - \iota^*} \right)^{-1+\alpha}$$

$$\psi(\iota^*) L^{1-\beta} = (1 - \iota^*)^{1-\alpha} \alpha^2 A m^{1/\alpha}$$

Because $\psi'(\cdot) > 0$, the left-hand side is strictly increasing in ι^* . Moreover, because $\alpha \in (0, 1)$, the right-hand side is strictly decreasing in ι^* . By the Inada conditions, $\lim_{z \uparrow 1} \psi(z) = +\infty$ and $\lim_{z \downarrow 0} \psi(z) = 0$. If $\iota^* = 0$, the right-hand side is strictly positive, whereas it is zero if $\iota^* = 1$. Hence, because both are trivially continuous, by the intermediate value theorem there exists at least one ι^* which verifies the equation. Since both are strictly monotone, ι^* is unique. \square

FIGURE D.1. EQUILIBRIUM OF THE MODEL

This figure plots the equilibrium of the model. The blue and red lines respectively display the left and right-hand side of the final equation of the proof of Proposition D.1. We assume $\psi(j) = \gamma j^2$ even though quadratic costs do not verify the Inada conditions.

Parametrization: $\alpha = .55$, $\beta = .45$, $\gamma = .2$, $A = .5$, $L = 1$, $m = .5$.

Proof of Implication D.1. From Lemma D.1, it is $m^{1/\alpha} = \psi(\iota^*)/(\alpha w)$, or

$$\alpha w m^{1/\alpha} = \psi(\iota^*)$$

Because $\psi'(\cdot) > 0$, an increase in w in the equilibrium implies an increase in $\psi(\iota^*)$, hence in ι^* . \square

Proof of Implication D.2. First note that because w is invariant across tasks, then by (D.3b) $e(j) = e$ for all j . Moreover, since the productivity of labor is constant across tasks, it is optimal to divide evenly L across the $(1 - \iota^*)$ non-automatized tasks. Therefore, by labor market clearing $e = L/(1 - \iota^*)$. Plug this in the left-hand side of (D.3b), yielding

$$w^{-\frac{1}{1-\alpha}} (\alpha A)^{\frac{1}{1-\alpha}} = \frac{L}{1 - \iota^*}$$

Using Lemma D.1 into the previous equation we get

$$\begin{aligned} \frac{\psi(\iota^*)}{\alpha m^{1/\alpha}} &= \left(\frac{L}{1 - \iota^*} \right)^{\alpha-1} \alpha A \\ L^{1-\alpha} &= \frac{(1 - \iota^*)^{1-\alpha}}{\psi(\iota^*)} \alpha^2 A m^{1/\alpha} \end{aligned}$$

Because $\alpha \in (0, 1)$ and $\psi'(\cdot) > 0$, the right-hand side is decreasing in ι^* . Therefore, an exogenous increase in L leads to an increase in the right-hand side, hence a decrease in ι^* . Following an increase in the labor supply, the share of automatized tasks decreases. \square

Proof of Implication D.3. Let $m_M > m_B$. From the previous proof, we have

$$\frac{L^{1-\alpha}}{\alpha^2 A m_i^{1/\alpha}} = \frac{(1 - t^*)^{1-\alpha}}{\psi(t^*)}$$

for $i = M, B$. Holding everything else constant, an increase in L translates into an increase in the left-hand side which is smaller if $m = m_M$ than under $m = m_B$ because $m_B, m_M \in (0, 1)$. Therefore, the right-hand side shall increase more under m_B . Hence, the compensating change in t^* is larger if $m = m_B$, i.e. in the relatively backward sector, than if $m = m_M$, i.e. in the relatively modern sector. \square

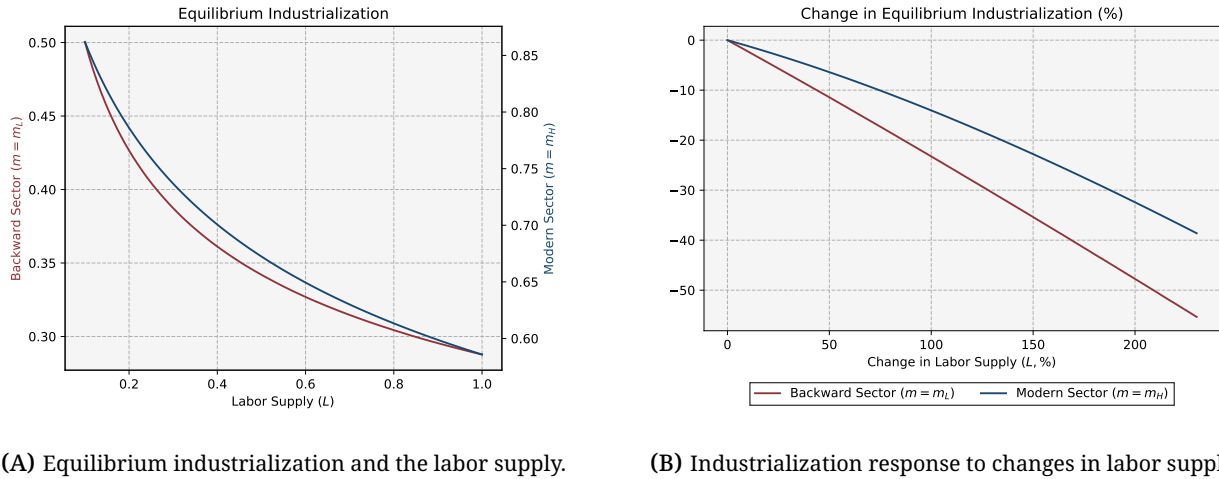

FIGURE D.2. INDUSTRIALIZATION AND LABOR SUPPLY

Notes. Figures plot the relationship between industrialization and the labor supply. The red and blue lines respectively display the backward and modern sectors. We assume $\psi(j) = \gamma j^2$ even though quadratic costs do not verify the Inada conditions.

Parametrization: $\alpha = .55$, $\beta = .45$, $\gamma = .2$, $A = .5$, $L = 1$, $m_H = .5$, $m_L = .2$.
